WILEY Blackwell

International Textbook of Diabetes Mellitus

International Textbook of Diabetes Mellitus

Fourth edition

Editors-In-Chief

Ralph A. DeFronzo MD

Professor of Medicine and Chief, Diabetes Division
The University of Texas Health Science Center at San Antonio (UTHSCSA)
Deputy Director, Texas Diabetes Institute
San Antonio, TX, USA

Ele Ferrannini MD

Professor of Internal Medicine
Department of Clinical and Experimental Medicine
University of Pisa
Pisa, Italy

Paul Zimmet AO, MD, PhD, FRACP, FRCP, FTSE

Director Emeritus, Victor Smorgon Diabetes Centre
Baker IDI Heart and Diabetes Institute
Adjunct Professor, Monash University
Honorary President, International Diabetes Federation
Chair, Programme Committee, World Diabetes Congress 2013
Melbourne, VIC, Australia

K. George M. M. Alberti MA, DPhil, PRCP, FRCPath, FRCP

Senior Research Investigator, Imperial College, London, UK
Chair of King's College Hospital NHS Foundation Trust
Emeritus Professor of Medicine, University of Newcastle upon Tyne
Newcastle upon Tyne, UK

WILEY Blackwell

Section Editors

Knut Borch-Johnsen MD, DMSc

Professor of Quality in Health Care
Medical Director, Holbæk Hospital
Holbaek, Denmark

Mark Cooper MD, PhD, FRACP

Deputy Director and Chief Scientific Officer
Baker IDI Heart and Diabetes Institute
Melbourne, VIC, Australia

Stefano Del Prato MD

Professor of Endocrinology and Metabolism
School of Medicine, University of Pisa;
Chief, Section of Diabetes and Metabolic Diseases
University of Pisa
Pisa, Italy

Robert H. Eckel MD

Charles A. Boettcher Endowed Chair in Atherosclerosis
Professor of Medicine
Division of Endocrinology, Metabolism and Diabetes, and Cardiology
Professor of Physiology and Biophysics
University of Colorado School of Medicine
Aurora, CO, USA

W. Timothy Garvey MD, FACE

Butterworth Professor and Chair,
Department of Nutrition Sciences
University of Alabama at Birmingham
Director, UAB Diabetes Research Center
GRECC Investigator and Staff Physician
Birmingham VA Medical Center
Birmingham, AL, USA

Rury R. Holman FRCP

Professor of Diabetic Medicine
Director, University of Oxford Diabetes Trials Unit
Oxford Centre for Diabetes, Endocrinology and Metabolism
Churchill Hospital
University of Oxford
Oxford, UK

Steven E. Kahn MB, ChB

Professor of Medicine
Division of Metabolism, Endocrinology and Nutrition
Director, Diabetes Research Center
University of Washington
VA Puget Sound Health Care System
Seattle, WA, USA

James B. Meigs MD

Massachusetts General Hospital
Boston, MA, USA

Eric Ravussin PhD

Associate Executive Director, Obesity & Diabetes
Pennington Biomedical Research Center
Baton Rouge, LA, USA

Jay S. Skyler MD, MACP

Professor of Medicine, Pediatrics, & Psychology
Division of Endocrinology, Diabetes, & Metabolism
Deputy Director — Diabetes Research Institute
University of Miami Miller School of Medicine
Miami, FL, USA

Hannele Yki-Järvinen MD, FRCP

Professor of Medicine
University of Helsinki;
Minerva Foundation Institute for Medical Research
Helsinki, Finland

Bernard Zinman CM, MD, FRCPC, FACP

Director, Leadership Sinai Centre for Diabetes
Sam and Judy Pencer Family Chair in Diabetes Research
Senior Scientist, Samuel Lunenfeld Research Institute
Professor of Medicine, University of Toronto Mount Sinai Hospital
Toronto, ON, Canada

Contents

Contributors

Muhammad Abdul-Ghani MD, PhD

Associate Professor
Diabetes Division
Department of Medicine
The University of Texas Health Science Center at San Antonio (UTHSCSA)
San Antonio, TX, USA

Sean H. Adams MS, PhD

Arkansas Children's Nutrition Center, and Section of Developmental Nutrition
Department of Pediatrics
University of Arkansas for Medical Sciences
Little Rock, AR, USA

Marilyn Ader PhD

Associate Director, Cedars-Sinai Diabetes and Obesity Research Institute
Associate Professor, Department of Biomedical Sciences
Cedars-Sinai
Los Angeles, CA, USA

Emma Ahlqvist PhD

Assistant Professor
Department of Clinical Sciences Malmö
Lund University
University Hospital Skåne
Malmö, Sweden

Intekhab Ahmed MD, FACP, FACE

Associate Professor of Medicine
Program Director Endocrine Fellowship
Division of Endocrinology, Diabetes and Metabolic Diseases
Jefferson Medical College, Thomas Jefferson University
Philadelphia, PA, USA

Bo Ahrén MD, PhD

Professor
Department of Clinical Sciences
Lund University
Lund, Sweden

R.A. Ajjan FRCP, MMedSci, PhD

Associate Professor/Consultant in Diabetes and Endocrinology
Division of Cardiovascular and Diabetes Research
University of Leeds/Leeds Teaching Hospitals Trust
Leeds, UK

Shamsa Ali MD

Assistant Professor of Endocrinology
Tulane University Health Sciences Center
New Orleans, LA, USA

Stephanie A. Amiel MD, FRCP

RD Lawrence Professor of Diabetic Medicine
Joint Head of Division of Diabetes & Nutritional Sciences
King's College London
London, UK

Ryan M. Anderson PhD

Assistant Professor
Department of Pediatrics
Indiana University School of Medicine,
Indianapolis, IN, USA

Arne Astrup MD, DMSc

Director and Professor
Department of Nutrition, Exercise and Sports
Faculty of Science
University of Copenhagen
Copenhagen, Denmark

Clifford J. Bailey PhD, FRCP (Edin), FRCPath

Professor of Clinical Science
School of Life and Health Sciences
Aston University
Birmingham, UK

Stephen C. Bain MA, MD, FRCP

Professor of Medicine (Diabetes)
Institute of Life Science, College of Medicine
Swansea University
Swansea, UK

Scott T. Baker MB.BS, PhD

Endocrinologist
Endocrine Centre & Department of Medicine
Austin Health;
University of Melbourne
Melbourne, VIC, Australia

George Bakris MD, FASH, FASN
Professor of Medicine
Director, ASH Comprehensive Hypertension Center
The University of Chicago
Chicago, IL, USA

Noël C. Barengo
Adjunct Professor
Department of Public Health
University of Helsinki
Helsinki, Finland

Anthony H. Barnett BSc (Hons), MD, FRCP
Consultant Physician and Emeritus Professor of Medicine
Clinical and Experimental Medicine
College of Medicine and Dentistry
University of Birmingham;
Diabetes Centre
Heart of England NHS Foundation Trust
Birmingham, UK

Richard N. Bergman PhD
Alfred Jay Firestein Chair in Diabetes Research
Director, Cedars-Sinai Diabetes and Obesity Research Institute
Professor, Department of Biomedical Sciences
Cedars-Sinai
Los Angeles, CA, USA

Wenche S. Borgnakke DDS, MPH, PhD
Senior Research Associate in Health Sciences
Department of Periodontics and Oral Medicine
University of Michigan School of Dentistry
Ann Arbor, MI, USA

Andrew J.M. Boulton MD, DSc (Hon), FRCP
President, European Association for the Study of Diabetes;
Professor of Medicine, University of Manchester;
Consultant Physician, Manchester Royal Infirmary
Manchester, UK;
Visiting Professor, University of Miami
Miami, FL, USA

Frank L. Bowling BSc(Hons), MSc, PhD, FFPM, RCPS (Glasg)
Clinical Research Fellow
University of Manchester
Manchester Royal Infirmary
Department of Diabetes & Vascular Surgery
Manchester, UK

Fernando Bril MD
Postdoctoral Associate
Division of Endocrinology, Diabetes & Metabolism
University of Florida
Gainesville, FL, USA

Shawn C. Burgess PhD
Associate Professor
Division Head, Metabolic Mechanisms of Disease
Advanced Imaging Research Center and Department of Pharmacology
University of Texas Southwestern Medical Center
Dallas, TX, USA

Sonia Caprio MD
Department of Pediatrics
Yale University School of Medicine
New Haven, CT, USA

Fabrizio Carinci MS
Senior Biostatistician
Serectrix snc
Pescara, Italy

William T. Cefalu MD
Executive Director
Douglas L. Manship, Sr. Professor of Diabetes
Pennington Biomedical Research Center
Louisiana State University
Baton Rouge, LA, USA

Ali J. Chakera MBChB, BMedSci (Hons)
Research Fellow
University of Exeter Medical School;
Royal Devon and Exeter Hospital
Exeter, UK

Juliana C.N. Chan MD
Professor of Medicine and Therapeutics
Department of Medicine and Therapeutics
Li Ka Shing Institute of Health Sciences
The Chinese University of Hong Kong
Hong Kong SAR, China

Xinpu Chen PhD
Postdoctoral Research Associate Baylor College of Medicine
Texas Children's Hospital and Baylor College of Medicine
Houston, TX, USA

Jean-Louis Chiasson MD
Professor of Medicine
Division of Endocrinology
Centre hospitalier de l'Université de Montréal (CHUM);
Research Centre, Centre Hospitalier de l'Université de Montréal, Montréal (CRCHUM),
Department of Medicine
Université de Montréal
Montréal, Canada

Alexandra Chisholm PhD
Senior Research Fellow
Department of Human Nutrition
University of Otago
Dunedin, New Zealand

Michael H. Cummings MD, FRCP
Professor of Diabetes and Endocrinology
Academic Department of Diabetes and Endocrinology
Queen Alexandra Hospitals Portsmouth NHS Trust
Portsmouth, UK

Kenneth Cusi MD, FACP, FACE
Professor of Medicine
Chief, Division of Endocrinology, Diabetes and Metabolism Division
University of Florida
Gainesville, FL, USA

Melanie J. Davies MD, FRCP, FRCGP
Professor of Diabetes Medicine
Leicester Diabetes Centre
College of Medicine, Biological Sciences and Psychology
University of Leicester;
National Institute for Health Research Leicester-Loughborough Diet
Lifestyle and Physical Activity
Biomedical Research Unit
Leicester, UK

Ralph A. DeFronzo MD
Professor of Medicine and Division Chief, Diabetes
Deputy Director, Texas Diabetes Institute
The University of Texas Health Science Center at San Antonio (UTHSCSA)
San Antonio, TX, USA

Alan M. Delamater PhD
Professor of Pediatrics and Psychology
Department of Pediatrics
University of Miami Miller School of Medicine
Miami, FL, USA

Stefano Del Prato MD
Professor of Endocrinology and Metabolism
School of Medicine, University of Pisa;
Chief, Section of Diabetes and Metabolic Diseases
University of Pisa
Pisa, Italy

Sridevi Devaraj PhD, DABCC, FACB
Medical Director of Clinical Chemistry and POCT;
Texas Childrens Hospital and Health Centers;
Professor of Pathology and Immunology
Baylor College of Medicine;
Director, Clinical Chemistry Fellowship
Associate Director, Translation, Texas Children's Microbiome Center
Suite, Houston, TX, USA

Jared M. Dickinson PhD
Assistant Professor
School of Nutrition and Health Promotion
Healthy Lifestyles Research Center
Exercise Science and Health Promotion
Arizona State University
Phoenix, AZ, USA

Elif I. Ekinci MBBS, FRACP, PhD
Director of Diabetes
Endocrine Centre & Department of Medicine
Austin Health;
University of Melbourne
Melbourne, VIC, Australia

Roy Eldor MD, PhD
Prin. Scientist
LSD Clinical Research Diabetes and Endocrinology
Merck Research Laboratories
Rahway, NJ, USA

Michael Erbach MD
Manager Medical Education
Sciarc Institute
Baierbrunn, Germany

Ele Ferrannini MD
Professor of Internal Medicine
Department of Clinical and Experimental Medicine
University of Pisa
Pisa, Italy

Hermes Florez MD, PhD, MPH
Professor of Medicine & Public Health Sciences
Chief, Division of Gerontology & Geriatric Medicine
Director, Division of Epidemiology & Population Health
University of Miami Miller School of Medicine
Director, GRECC-Miami VA Healthcare System
Miami, FL, USA

Colleen Flynn, MD
Assistant Professor of Medicine
Department of Medicine, Section of Endocrinology, Diabetes and Metabolism
The University of Chicago
Chicago, IL, USA

Vivian Fonseca MD
Professor of Medicine & Pharmacology
Chief, Section of Endocrinology
Tulane University Health Sciences Center
New Orleans, LA, USA

Josephine M. Forbes BSc, PhD
Principal Research Fellow and Professor of Medicine
Group Leader, Glycation and Diabetes
Program Chief, Cardiovascular and Metabolic Diseases
Mater Research Institute, The University of Queensland
Brisbane, QLD Australia

Henrik Galbo MD
Professor
Institute of Inflammation Research
Department of Rheumatology, Rigshospitalet
University of Copenhagen
Copenhagen, Denmark

Emily Jane Gallagher, MD

Assistant Professor
Division of Endocrinology, Diabetes and Bone Diseases
Icahn School of Medicine at Mount Sinai (ISMMS)
New York, NY, USA

Alan J. Garber MD, PhD, FACE

Professor
Departments of Medicine,
Molecular and Cellular Biology
Baylor College of Medicine
Houston, TX, USA

W. Timothy Garvey MD, FACE

Butterworth Professor and Chair,
Department of Nutrition Sciences
University of Alabama at Birmingham
Director, UAB Diabetes Research Center
GRECC Investigator and Staff Physician
Birmingham VA Medical Center
Birmingham, AL, USA

Robert J. Genco DDS, PhD

Distinguished Professor of Oral Biology and Microbiology
State University of New York at Buffalo
Buffalo, NY, USA

Susan M. Gerber MD

Assistant Professor of Medicine
Cooper Medical School of Rowan University
Cooper University Health Care
Camden, NJ, USA

Timothy Gilbertson PhD

Professor
Department of Biology
Utah State University
Logan, UT, USA

Henry N. Ginsberg MD

Irving Professor of Medicine
Department of Medicine
Director, Irving Institute for Clinical and Translational Research
Columbia University College of Physicians and Surgeons
New York, NY, USA

Peter J. Grant MD, FRCP, FMedSci

Professor of Medicine
Honorary Consultant Physician, LTHT
Division of Cardiovascular and Diabetes Research
Multidisciplinary Cardiovascular Research Centre
University of Leeds
Leeds, UK

Leif Groop MD

Professor of Endocrinology
Department of Clinical Sciences Malmö
Lund University
University Hospital Skåne
Malmö, Sweden;
Finnish Institute for Molecular Medicine (FIMM)
University of Helsinki
Helsinki, Finland

Eran Hadar MD

Division of Maternal Fetal Medicine
Helen Schneider Hospital for Women
Rabin Medical Center
Petah-Tiqva, Israel

Markolf Hanefeld MD, PhD

Professor of Internal Medicine
Study Centre Prof. Hanefeld
Section Endocrinology and Metabolism
GWT-Technical University
Dresden, Germany

Brooke Harcourt BSc (Hons), PhD

Mater Medical Research Institute
South Brisbane, Australia;
Department of Medicine and Immunology
Monash University
Melbourne, VIC, Australia

Andrew T. Hattersley DM, FRCP, FRS

Professor of Molecular Medicine
University of Exeter Medical School;
Royal Devon and Exeter Hospital
Exeter, UK

Robert R. Henry MD

Chief, Section of Diabetes/Metabolism
VA San Diego HealthCare System;
Professor of Medicine
University of California at San Diego,
San Diego, CA, USA

Jennifer Hernandez MS

Research Associate
Department of Pediatrics
University of Miami Miller School of Medicine
Miami, FL, USA

Irl B. Hirsch MD

Professor of Medicine
University of Washington School of Medicine
University of Washington Medical Center-Roosevelt
Seattle, WA, USA

Moshe Hod MD

Professor of Obstetrics and Gynecology
Director, Division of Maternal Fetal Medicine
Helen Schneider Hospital for Women
Rabin Medical Center
Petah-Tiqva, Israel

Michael Horowitz MBBS, PhD, FRACP

Director, Endocrine & Metabolic Unit
Royal Adelaide Hospital;
Professor of Medicine and Leader
Centre of Research Excellence (CRE) in Translating Nutritional Science to Good Health
Discipline of Medicine
University of Adelaide
Adelaide, SA, Australia

Tamas L. Horvath DVM, PhD

Professor & Chair
Section of Comparative Medicine
Jean and David W. Wallace Professor of Biomedical Research
Professor of Neurobiology and Ob/Gyn
Director, Yale Program in Integrative Cell Signaling and Neurobiology of Metabolism
New Haven, CT, USA

Daniel S. Hsia MD

Assistant Professor
Pennington Biomedical Research Center
Louisiana State University
Baton Rouge, LA, USA

Rebecca L. Hull PhD

Research Associate Professor
Division of Metabolism, Endocrinology and Nutrition
Department of Medicine,
VA Puget Sound Health Care System and University of Washington
Seattle, WA, USA

Giuseppina Imperatore

Centers for Disease Control and Prevention
National Center for Chronic Disease Prevention and Health Promotion
Atlanta, GA, USA

Concetta Tania Di Iorio MPH

Legal Expert
Serectrix snc
Pescara, Italy

Serge A. Jabbour MD, FACP, FACE

Professor of Medicine
Director, Division of Endocrinology, Diabetes & Metabolic Diseases
Jefferson Medical College
Thomas Jefferson University
Philadelphia, PA, USA

George Jerums MBBS MD FRACP

Endocrinologist
Endocrine Centre & Department of Medicine
Austin Health;
University of Melbourne
Melbourne, VIC, Australia

Steven E. Kahn MB, ChB

Professor of Medicine
Division of Metabolism, Endocrinology and Nutrition
Director, Diabetes Research Center
University of Washington
VA Puget Sound Health Care System
Seattle, WA, USA

M. Ann Kelly BSc (Hons), PhD

Senior Scientist
Clinical and Experimental Medicine, College of Medicine and Dentistry
University of Birmingham;
Diabetes Centre
Heart of England NHS Foundation Trust
Birmingham, UK

Grace Kim MD

Post-doctoral Fellow
Department of Pediatrics
Yale University School of Medicine
New Haven, CT, USA

Abbas E. Kitabchi PhD, MD, FACP, FACE

Professor of Medicine and Molecular Sciences
Maston K. Callison Professor of Medicine
The University of Tennessee Health Science Center
Memphis, TN, USA

Alice P.S. Kong MBChB, MD, MRCP, FRCP

Associate Professor
Department of Medicine and Therapeutics
Li Ka Shing Institute of Health Sciences
The Chinese University of Hong Kong
Hong Kong SAR, China

Paul R. Langlais PhD

Assistant Professor
Department of Biochemistry and Molecular Biology
College of Medicine
Mayo Clinic in Arizona
Scottsdale, AZ, USA

Harold E. Lebovitz MD, FACE

Professor of Medicine
State University of New York Health Science Center at Brooklyn
Staten Island, NY, USA

Pierre J. Lefèbvre MD, PhD, FRCP, MAE

Emeritus Professor of Medicine
University of Liège;
Consultant Physican at University Hospital
CHU Sart Tilman
Liège, Belgium

Derek LeRoith MD, PhD

Professor of Medicine and
Director of Research
Division of Endocrinology, Diabetes & Bone Diseases
Icahn School of Medicine at Mount Sinai (ISMMS)
New York, NY, USA

José e Leroux-Stewart MD

Division of Endocrinology
Centre hospitalier de l'Université de Montréal
Institut de Recherches Cliniques de Montréal (IRCM)
Montréal, QC, Canada

Romina Lomonaco MD

Assistant Professor
Division of Endocrinology, Diabetes & Metabolism
University of Florida
Gainesville, FL, USA

Richard J. MacIsaac Bsc (Hons), PhD, MBBS, FRACP

Professor and Director
Department of Endocrinology & Diabetes
St Vincent's Hospital & University of Melbourne
Melbourne, VIC, Australia

Dianna J. Magliano BAppSci (Hons), MPH, PhD

Associate Professor and Senior Epidemiologist
Baker IDI Heart and Diabetes Institute
Melbourne, VIC, Australia

Rayaz Malik BSc (Hons), MBChB, PhD, FRCP

Professor of Medicine
Weill Cornell Medical College
Qatar Foundation
Education City
Doha, Qatar

Lawrence J. Mandarino PhD

Division of Endocrinology
Mayo Clinic in Arizona
Scottsdale, AZ;
Center for Metabolic and Vascular Biology
Arizona State University
Tempe, AZ, USA

Jim I. Mann CNZM, MA, DM, PhD, FRACP, FRSNZ

Professor in Human Nutrition and Medicine
Department of Human Nutrition;
Director, Edgar Diabetes and Obesity Research Centre
University of Otago
Dunedin, New Zealand

Chinmay S. Marathe MBBS

Advanced Trainee in Endocrinology
Royal Adelaide Hospital
Research Fellow
Centre of Research Excellence (CRE) in Translating Nutritional Science to Good Health
Discipline of Medicine, University of Adelaide
Adelaide, SA, Australia

Ashley Marchante BS

Graduate Research Assistant
Department of Pediatrics
University of Miami Miller School of Medicine
Miami, FL, USA

Piero Marchetti

Associate Professor of Endocrinology
Department of Endocrinology
University of Pisa
Pisa, Italy

Andrea Mari BEng

Professor of Internal Medicine
Institute of Neuroscience
National Research Council
Padova, Italy

Massimo Massi Benedetti MD

President and Scientific Director
Hub for International Health ReSearch HIRS
IDF Senior Programme Adviser
Perugia, Italy

Teresa L. Mastracci PhD

Research Assistant Professor
Department of Pediatrics
Indiana University School of Medicine
Indianapolis, IN, USA

Karl Matz

Chief Physician
Danube University of Krems
Krems, Austria

Donald A. McClain MD, PhD

Department of Medicine
University of Utah and Veterans Affairs Medical Center
Salt Lake City, UT, USA

Juris J. Meier MD, FRCP Edin.

Division of Diabetes and Gastrointestinal Endocrinology
University Hospital St. Josef-Hospital
Ruhr-University Bochum Gudrunstr.
Bochum, Germany

Arne Melander MD, PhD
Professor Emeritus of Clinical Pharmacology
Lund University
Lund and Malmö, Sweden

Kohtaro Minami PhD
Associate Professor
Division of Cellular and Molecular Medicine
Kobe University Graduate School of Medicine
Kobe, Japan

Raghavendra G. Mirmira MD, PhD
Lilly Professor of Pediatric Diabetes
Professor of Pediatrics, Medicine, Physiology, and Biochemistry
Director, Diabetes Research Center
Director, Medical Scientist Training Program
Indiana University School of Medicine
Indianapolis, IN, USA

M. Mojaddidi MBChB, PhD
Dean of Taibah University Research & Consulting Institute
Taibah University
Al-Madinah Al-Munawarah
Saudi Arabia

Sunder Mudaliar MD, FRCP (Edin), FACP, FACE
Clinical Professor of Medicine
University of California at San Diego;
Staff Physician
Section of Diabetes/Metabolism
VA San Diego Healthcare System
San Diego, CA, USA

Debabrata Mukherjee, MD, FACC, FAHA, FSCAI
Chairman, Department of Internal Medicine;
Chief, Cardiovascular Medicine
Professor of Internal Medicine
Texas Tech University
El Paso, TX, USA

Medha Munshi MD
Director of the Geriatric Diabetes Clinic
Joslin Diabetes Center
Beth Israel Deaconess Medical Center
Department of Medicine
Harvard Medical School
Boston, MA, USA

Mary Beth Murphy RN, MS, CDE, MBA, CCRP
Research Nurse Director
The University of Tennessee Health Science Center
Memphis, TN, USA

K.M. Venkat Narayan
Centers for Disease Control and Prevention
National Center for Chronic Disease Prevention and Health Promotion
Atlanta, GA, USA

Andrea Natali MD
Professor of Internal Medicine
Department of Clinical and Experimental Medicine
Section of Internal Medicine
University of Pisa
Pisa, Italy

Michael A. Nauck MD
Professor of Internal Medicine
Division of Diabetology and Gastrointestinal Endocrinology
Medical Department 1
St. Josef-Hospital
Ruhr-University Bochum
Bochum, Germany

Karl J. Neff MB, MRCPI
Clinical Research Fellow
Diabetes Complications Research Centre
Conway Institute of Biomolecular and Biomedical Research
University College Dublin
Dublin, Ireland

John W. Newman PhD
Research Chemist, Obesity & Metabolism Research Unit
United States Department of Agriculture-Agricultural Research Service
Western Human Nutrition Research Center -and-
Adjunct Associate Professor, Department of Nutrition
University of California
Davis, CA, USA

Ruslan Novosyadlyy MD, PhD
VP
Department of Oncology—Translational Medicine
ImClone Systems, a wholly-owned subsidiary of Eli Lilly and Company
Alexandria Center for Life Science
New York, NY, USA

Kwame Ntim MD
Assistant Professor
Division of Endocrinology, Diabetes & Metabolism
University of Florida
Gainesville, FL, USA

Miladys M. Palau-Collazo MD
Pediatric Endocrine Fellow
Department of Pediatrics
Yale University School of Medicine
New Haven, CT, USA

Sianna Panagiotopoulos PhD
Manager of Research
Endocrine Centre & Department of Medicine
Austin Health;
University of Melbourne
Melbourne, VIC, Australia

Mie Jung Park-York PhD
Research Assistant Professor
Department of Biology
Utah State University
Logan, UT, USA

Liza Phillips MBBS (Hons), PhD, MS, FRACP
Postdoctoral Research Fellow
Royal Adelaide Hospital / Centre of Research Excellence (CRE) in Translating Nutritional Science to Good Health
Discipline of Medicine, University of Adelaide
Adelaide, SA, Australia

Jorge Plutzky MD
Director, The Vascular Disease Prevention Program
Preventive Cardiology, Cardiovascular Division
Brigham and Women's Hospital
Boston, MA, USA

Vincent Poitout DVM, PhD, FCAHS
Professor of Medicine
Montreal Diabetes Research Center, CRCHUM;
Departments of Medicine and Biochemistry
Université de Montréal
Montréal, QC, Canada

David Preiss MD, PhD
Clinical Senior Lecturer
Institute of Cardiovascular and Medical Sciences
BHF Glasgow Cardiovascular Research Centre
University of Glasgow
Glasgow, UK

Erosha Premaratne MBBS, MD, FRACP
Endocrinologist
Endocrine Centre & Department of Medicine
Austin Health;
University of Melbourne
Melbourne, VIC, Australia

Alberto Pugliese MD
Professor of Medicine, Immunology and Microbiology
Division of Diabetes, Endocrinology and Metabolism
Head, Immunogenetics Program
Diabetes Research Institute
University of Miami Miller School of Medicine
Miami, FL, USA

Qing Qiao
Adjunct Professor
Department of Public Health
University of Helsinki;
National Public Health Institute
Helsinki, Finland

Ré mi Rabasa-Lhoret MD, PhD
Associate Professor
Division of Endocrinology
Centre hospitalier de l'Université de Montréal (CHUM);
Department of Nutrition
Université de Montréal
Institut de Recherches Cliniques de Montréal (IRCM)
Montréal, QC, Canada

Rajesh Rajendran MBBS, AHEA, MRCP(UK)
Specialist Registrar in Diabetes and Endocrinology
Academic Department of Diabetes and Endocrinology
Queen Alexandra Hospitals
Portsmouth NHS Trust
Portsmouth, UK

Daiva Rastenyte
Professor
Lithuanian University of Health Sciences
Kaunas, Lithuania

Eric Ravussin PhD
Professor and Douglas L. Gordon Chair in Diabetes & Metabolism
Associate Executive Director, Clinical Sciences
Director, Nutrition Obesity Research Center
Pennington Biomedical Research Center
Louisiana State University
Baton Rouge, LA, USA

Simon D. Rees BSc, PhD
Postdoctoral Research Fellow
Clinical and Experimental Medicine
College of Medicine and Dentistry
University of Birmingham;
Diabetes Centre
Heart of England NHS Foundation Trust
Birmingham, UK

Marian J. Rewers MD, PhD
Professor of Pediatrics & Medicine
Executive Director
Barbara Davis Center for Childhood Diabetes
University of Colorado Denver
Aurora, CO, USA

Gissette Reyes-Soffer MD
Assistant Professor of Medicine
Department of Medicine
Division of Preventive Medicine and Nutrition
Columbia University College of Physicians and Surgeons
New York, NY, USA

Christopher J. Rhodes BSc (Hons), PhD
Professor, Research Director and Chair of Committee on Molecular Metabolism
Kovler Diabetes Center
University of Chicago
Chicago, IL, USA

Erik A. Richter MD, DM Sci

Professor of Human Physiology and Exercise Physiology

Molecular Physiology Group

Department of Nutrition, Exercise and Sports

Faculty of Science, University of Copenhagen

Copenhagen, Denmark

R. Paul Robertson MD

Professor of Medicine and Pharmacology

University of Washington;

Professor of Medicine

University of Minnesota;

President Emeritus

Pacific Northwest Diabetes Institute

Seattle, WA, USA

Arlan L. Rosenbloom MD

Adjunct Distinguished Service Professor Emeritus

University of Florida College of Medicine

Department of Pediatrics

Gainesville, FL, USA

Carel W. le Roux MBChB, FRCP, FRCPath, PhD

Diabetes Complications Research Centre

Conway Institute

University College Dublin

Dublin, Ireland

Jorge Ruiz MD

Associate Director for Education and Evaluation

GRECC-Miami VAHS

Division of Geriatric Medicine, Departments of Medicine

University of Miami Miller School of Medicine

Miami, FL, USA

Susan L. Samson MD, PhD, FRCPC, FACE

Assistant Professor

Department of Medicine

Baylor College of Medicine

Houston, TX, USA

Naveed Sattar MBChB, PhD, FRCP (Glas), FRCPath

Professor of Metabolic Medicine

Institute of Cardiovascular and Medical Sciences

BHF Glasgow Cardiovascular Research Centre

University of Glasgow

Glasgow, UK

Oliver Schnell MD, PhD

Executive Member of the Managing Boardof the Forschergruppe Diabetes

e.V. at the Helmholtz Center

Munich

Munich—Neuherberg, Germany

Susumu Seino MD, DM Sci

Professor and Head

Division of Molecular and Metabolic Medicine

Department of Physiology and Cell Biology

Kobe University Graduate School of Medicine

Kobe, Japan

A.K. Sharma BVSc., PhD

Professor of Anatomy

Uttaranchal Ayurvedic Medical College

Dehradun, India

Jonathan E. Shaw MD, FRACP, FRCP (UK)

Associate Director and Associate Professor

Baker IDI Heart and Diabetes Institute

Melbourne, VIC, Australia

Tadao Shibasaki PhD

Assistant Professor

Division of Cellular and Molecular Medicine

Kobe University Graduate School of Medicine

Kobe, Japan

Jay S. Skyler MD, MACP

Professor of Medicine, Pediatrics, & Psychology

Division of Endocrinology, Diabetes, & Metabolism

Deputy Director - Diabetes Research Institute

University of Miami Miller School of Medicine

Miami, FL, USA

Eberhard Standl MD, PhD

Professor of Medicine

Munich Diabetes Research Group e.V.

Helmholtz Centre

Munich, Germany

Andrea K. Steck MD

Assistant Professor of Pediatrics

Barbara Davis Center for Childhood Diabetes

University of Colorado Denver

Aurora, CO, USA

Roland Stein PhD

Professor

Vanderbilt University Medical Center

Nashville, TN, USA

Douglas F. Stickle PhD, DABCC, FACB

Professor, Department of Pathology

Director, Chemistry and POCT

Jefferson Medical College,Thomas Jefferson University

Philadelphia, PA, USA

Bernd Stratmann PhD
Research Director Diabetes Center
Heart and Diabetes Center NRW
University Clinic Ruhr University
Bochum, Germany

Abd A. Tahrani MD, MRCP, MMedSci, PhD
NIHR Clinician Scientist
Head of Weight Management Services
Honorary Consultant in Endocrinology and Diabetes
Centre of Endocrinology, Diabetes and Metabolism (CEDAM)
School of Clinical and Experimental Medicine
University of Birmingham
Birmingham, UK

Charmaine S. Tam, PhD
Postdoctoral Fellow
Pennington Biomedical Research Center
Louisiana State University
Baton Rouge, LA, USA;
The Charles Perkins Centre and School of Biological Sciences,
University of Sydney
Sydney, NSW, Australia

William V. Tamborlane MD
Professor and Chief of Pediatric Endocrinology
Yale School of Medicine and the Yale Center for Clinical Investigation
New Haven, CT, USA

Gavin S. Tan MBBS (S'pore), MMed (Ophth), FRCSEd (Ophth), FAMS
Consultant & Assistant Professor
Vitreo-Retinal Service
Singapore National Eye Centre;
Singapore Eye Research Institute
Duke-NUS Graduate Medical School
Singapore

Yoel Toledano MD
Division of Maternal Fetal Medicine
Helen Schneider Hospital for Women
Rabin Medical Center
Petah-Tiqva, Israel

Dace L. Trence MD
Professor of Medicine
University of Washington Medical Center
Seattle, WA, USA

Diethelm Tschoepe MD, FESC
Professor of Medicine
Medical Director Diabetes Center
Heart and Diabetes Center NRW
University Clinic Ruhr University
Bochum, Germany

Jaakko Tuomilehto MD, MA (sociol), PhD, FRCP (Edin), FESC
Professor
Department of Public Health
University of Helsinki;
National Public Health Institute
Helsinki, Finland;
Danube University of Krems
Krems, Austria;
King Abdulaziz University
Jeddah, Saudi Arabia

Guillermo E. Umpierrez MD
Professor of Medicine
Department of Medicine, Division of Endocrinology and Metabolism
Emory University School of Medicine
Chief of Diabetes and Endocrinology,
Grady Health System
Atlanta, GA, USA

Luis Varela
Program in Integrative Cell Signalling and Neurobiology of Metabolism
Section of Comparative Medicine
Yale University School of Medicine
New Haven, CT, USA

Elena Volpi, MD, PhD
Daisy Emery Allen Distinguished Chair in Geriatric Medicine
Director ad interim, Sealy Center on Aging
Associate Director, Institute for Translational Sciences
University of Texas Medical Branch
Galveston, TX, USA

Paul Welsh PhD
British Heart Foundation Research Fellow
Institute of Cardiovascular and Medical Sciences
BHF Glasgow Cardiovascular Research Centre
University of Glasgow
Glasgow, UK

Desmond E. Williams
Centers for Disease Control and Prevention
National Center for Chronic Disease Prevention and Health Promotion
Atlanta, GA, USA

Rhys Williams MA, PhD, FFPH, FRCP
Emeritus Professor of Clinical Epidemiology
Swansea University
Swansea, UK

Tien Yin Wong MBBS, MMED (Ophth), MPH, PhD, FRCSE, FRANZCO, FAMS
Provost Chair Professor of Ophthalmology
Singapore Eye Research Institute, Singapore National Eye Centre
Chairman, Department of Ophthalmology
National University of Singapore & National University Hospital
Vice-Dean, Office of Clinical Sciences
Duke NUS Graduate Medical School
Singapore

Thomas Yates PhD, MSc, BSc
Reader in Physical Activity, Sedentary Behaviour and Health
Leicester Diabetes Centre
College of Medicine, Biological Sciences and Psychology
University of Leicester;
National Institute for Health Research Leicester-Loughborough Diet, Lifestyle
and Physical Activity
Biomedical Research Unit
Leicester, UK

Hannele Yki-Järvinen MD, FRCP
Professor of Medicine
University of Helsinki
Minerva Foundation Institute for Medical Research
Helsinki, Finland

David A. York PhD
Professor
Department of Biology
Utah State University
Logan, UT, USA

Barak Zafrir, MD
Preventive Cardiology, Cardiovascular Division
Brigham and Women's Hospital
Boston, MA, USA;
Department of Cardiovascular Medicine

Preface

As the epidemic of diabetes continues to expand in parallel with the rapid spread of obesity, healthcare providers strive to find interventions to reduce the morbidity, mortality, and rising costs associated with this devastating disease, which ravages both the micro- and the macrovasculature. Although the increase in incidence of type 2 diabetes may be attributed to the expanding girth of the population coupled with a lack of physical activity, the marked increase in the incidence of type 1 diabetes remains unexplained. Our knowledge of the cellular, biochemical, and molecular etiology of impaired insulin action and beta-cell failure has expanded enormously, but the genetic basis of both type 1 and type 2 diabetes and their associated complications is still by and large undefined. Despite the introduction of multiple new classes of antidiabetic agents for the treatment of type 2 diabetes, and newer insulin preparations, insulin delivery systems, and glucose-sensing devices for the management of type 1 diabetes, glycemic control is suboptimal in approximately half of all diabetic patients and the excess risk for macrovascular complications is largely unexplained. In many parts of the world, these treatment advances are not available and instituting behavioral modification programs at the societal and individual level is proving to be inadequate in curbing the growing epidemic of obesity. Whether the introduction of novel weight loss medications will stem the tide of obesity remains to be determined.

The fourth edition of the *International Textbook of Diabetes Mellitus* will continue to be the most widely referenced textbook of diabetes worldwide and draws upon the expertise of leading basic scientists, clinicians, educators, and healthcare professionals globally to provide the most updated information on advances in diabetes research and clinical care. This information will be an invaluable resource and provide the practicing physician, as well as the basic scientist and clinical investigator, with the requisite resources to advance them to the frontiers of biomedical research in the fields of diabetes, metabolism, and obesity and to provide them with state-of-the-art knowledge to optimize clinical care for their diabetic patients.

Ralph A. DeFronzo, MD

SECTION I

Epidemiology

CHAPTER 1

Classification of diabetes mellitus and other categories of glucose intolerance

Dianna J. Magliano, Paul Zimmet and Jonathan E. Shaw

Baker IDI Heart and Diabetes Institute, Melbourne, VIC, Australia

Key points

- The classification and diagnosis of diabetes is based on etiology and not on pharmacologic treatment.
- Diagnoses of diabetes are made using fasting plasma glucose, 2-hour postchallenge of glucose or HbA1c.
- Differentiation between type 1 and type 2 diabetes is usually straightforward but can be difficult among obese children and adults.
- Precise diagnoses of certain monogenic diabetes using genetic testing can be useful as the outcomes can influence treatment decisions.
- A range of commonly used drugs such as statins and glucocortocoid steroids can lead to the development of diabetes.

Introduction

A critical requirement for orderly epidemiologic, genetic and clinical research, and indeed for the management of diabetes mellitus and other forms of glucose intolerance is an appropriate classification system. Furthermore, a hallmark in the process of understanding the etiology of a disease and studying its natural history is the ability to identify and differentiate its various forms and place them into a rational etiopathologic framework. While there have been a number of sets of nomenclature and diagnostic criteria proposed for diabetes, no systematic categorization existed until the mid 1960s [1]. Now diabetes mellitus is recognized as being a syndrome, a collection of disorders that have hyperglycemia and glucose intolerance as their hallmark, due either to insulin deficiency or to impaired effectiveness of insulin's action, or to a combination of these.

Historical perspective and current classifications

Previous classifications

In 1965, an Expert Committee on Diabetes Mellitus published the first World Health Organization (WHO) report on diabetes classification [1]. The report includes one of the first attempts at international consensus on a classification. They decided to classify diabetes: " … *based on the age of recognized onset, which seemed to be the only reliable means of classification for universal use.*"

The report also recognized certain specific types of diabetes including brittle, insulin-resistant, gestational, pancreatic, endocrine, and iatrogenic diabetes. Since then, several pathogenic mechanisms have been described and long-term studies have shown different courses and outcomes of different types of diabetes.

A revised classification of glucose intolerance, was formulated by the National Diabetes Data Group (NDDG) [2]. This was amended and adopted in the second report of the WHO Expert Committee in 1980 [3] and in a modified form in 1985. The 1980 Expert Committee proposed two major classes of diabetes mellitus and named them insulin-dependent diabetes mellitus (IDDM) or type 1, and non-insulin-dependent diabetes mellitus (NIDDM) or type 2 [3]. In the 1985 Study Group Report, the terms type 1 and type 2 were omitted, but the classes IDDM and NIDDM were retained and a new class of malnutrition-related diabetes mellitus (MRDM) was introduced [4]. The 1985 WHO classification was essentially based on clinical descriptions, with a specific focus on the pharmacologic management of patients (i.e., insulin-dependent, non-insulin-dependent, gestational). The question as to whether certain clinical forms

of diabetes (such as the so-called "tropical diabetes") had been given adequate priority to correct hierarchic order that was raised many years before probably led to the introduction of MRDM, although more precise epidemiologic data and a better assessment were needed, and called for.

Both the 1980 and 1985 reports included other types of diabetes and impaired glucose tolerance (IGT) as well as gestational diabetes mellitus (GDM). The 1985 classification was widely accepted and used internationally, and represented a compromise between clinical and etiological classifications. Furthermore, it permitted classification of individual patients in a clinically useful manner even when the specific etiology was unknown. The 2011 American Diabetes Association (ADA) [5] classifications or staging of diabetes still include clinical descriptive criteria but a complementary classification according to etiology is recommended by both organizations.

In 1999, the WHO incorporated an approach developed by Kuzuya and Matsuda [6], which clearly separated the criteria related to etiology from those related to the degree of deficiency of insulin or insulin action, and defined each patient on the basis of these two sets of criteria (Figure 1.1). It is now well established that diabetes may progress through several clinical stages during its natural history, quite independent of its etiology. The clinical staging reflects this and, indeed, individuals may move from one stage to another stage in both directions (Figure 1.1). Even if there is no information concerning the underlying etiology, persons with diabetes or those who are developing the disease can be categorized by stage according to clinical characteristics.

Current classification

The current classification allows for various degrees of hyperglycemia in individuals irrespective of the disease process. These are glycemic stages ranging from normoglycemia (normal glucose tolerance) to hyperglycemia where insulin is required for survival. All individuals with the disease can be categorized according to clinical stage [7]. The stage of glycemia may change over time depending on the extent of the underlying disease processes. As shown in Figure 1.1, the disease process may be present but may not have progressed far enough to cause hyperglycemia. The etiological classification is possible as the defect or process which may lead to diabetes may be identified at any stage in the development of diabetes, even at the stage of normoglycemia. As an example, the presence of islet cell antibodies (ICA) and/or antibodies to glutamic acid decarboxylase (anti-GAD) [8] in a normoglycemic individual indicates the autoimmune process, which underlies type 1 diabetes, is present, although the individual may or may not ultimately develop diabetes [7.9]. For type 2 diabetes, there are few useful highly specific indicators, though the presence of risk factors such as obesity indicates the likelihood of developing type 2 diabetes. Hopefully, future research will reveal some specific markers of the type 2 diabetes disease process.

Stages / Types	Normoglycemia Normal glucose tolerance	Hyperglycemia			
		IGT and/or IFG	Diabetes Mellitus		
			Not insulin requiring	Insulin: for control	Insulin: for survival
Type 1 • Autoimmune • Idiopathic	←——————————————————————————→				
Type 2 • Predom. • insulin resistance • Predom. insulin secretory defects	←————————————————→			- - - →	
Other specific types • Genetic defects of β-cell function • Genetic defects of insulin action • Diseases of exocrine pancreas • Endocrinopathies • Drug or chemical induced • Others	←————————————————→			- - - →	
Gestational hyperglycemia	←————————————————→			- - - →	

Figure 1.1 Disorders of glycemia: etiologic types and clinical stages. Source: World Health Organization 1999 [7]. Reproduced with permission of the WHO.

The same disease process can cause various degrees of impaired glucose metabolism such as impaired fasting glycemia (IFG) and impaired glucose tolerance (IGT) without fulfilling the criteria for the diagnosis of diabetes [7]. Weight reduction, exercise and/or oral hypoglycemic therapy can achieve satisfactory glycemic control in some persons with type 2 diabetes. These persons, therefore, do not require insulin initially but may do so much later in their course as β-cell function deteriorates. Some persons require insulin for adequate glycemic control at an earlier stage in type 2 diabetes but could survive without it. By definition these persons have some residual insulin secretion. Patients with extensive β-cell destruction (minimal residual insulin secretion) do require insulin for survival and this is the hallmark of type 1 diabetes [7,9].

The classification by etiological type (Table 1.1) results from improved understanding of the causes of diabetes, although this is still far from complete, particularly for type 1 diabetes.

The terms "insulin-dependent diabetes mellitus," "non-insulin-dependent diabetes mellitus" and their acronyms "IDDM" and "NIDDM" have been removed from classifications. These terms were very confusing and frequently resulted in misclassification, as patients were classified on the basis of their treatment, and indeed their age, rather than on pathogenesis. In the current classification, the terms "type 1" and "type 2" are retained (using Arabic rather than Roman numerals) [7].

Type 1 includes those cases attributable to an autoimmune process (although the basic precipitating cause of this process is still unknown), as well as those with β-cell destruction for which neither an etiology nor a pathogenesis is known (idiopathic). Those forms of β-cell destruction or failure to which specific causes can be assigned (e.g. cystic fibrosis, mitochondrial defects) are not included in this type of diabetes. These issues are discussed in greater detail later.

Type 2 includes the common major form of diabetes which results from defect(s) in insulin secretion and/or from insulin resistance, and often a combination of both. Malnutrition-related diabetes (MRDM) is no longer part of the WHO classification [7]. Of its two subtypes, protein-deficient pancreatic diabetes (PDPD or PDDM) needs more studies for a better definition. The other former subtype of MRDM, fibrocalculous pancreatic diabetes (FCPD), is now classified as a disease of the exocrine pancreas labeled "fibrocalculous pancreatopathy", which may lead to diabetes.

Impaired glucose tolerance (IGT) and impaired fasting glycemia (IFG) are classified as stages of impaired glucose regulation, since they can be observed in any hyperglycemic disorder.

Gestational diabetes is a state of glucose intolerance first recognized during pregnancy which usually resolves after delivery but is associated with later increased long-term risk of type 2 diabetes. It encompasses the groups formerly classified as gestational impaired glucose tolerance (GIGT) and gestational diabetes mellitus (GDM) [7].

DIABETES TYPES

Type 1 process

Type 1 indicates the processes of β-cell destruction that may ultimately lead to diabetes in which insulin is required for survival in order to prevent the development of ketoacidosis, coma, and death. This category comprises:

- *Immune-mediated diabetes mellitus*: This is the classical form of type 1 diabetes, which can occur at any age, and results from a cell-mediated autoimmune destruction of the pancreatic β cells. The type 1 process is characterized by the presence of ICA, anti-GAD, islet antigen 2 (IA2) or insulin autoantibodies which identify the autoimmune process associated with β-cell destruction [9]. Other autoimmune disorders such as Grave's disease, Hashimoto's thyroiditis and Addison's disease may be associated with type 1 diabetes mellitus [9].

  The rate of β-cell destruction is quite variable, typically being rapid in children and slower in adults. Typically, type 1 diabetes requires insulin therapy from the time of presentation in both adults and children, but a slowly progressive form, latent autoimmune diabetes in adults (LADA), is well described [8]. Blood glucose in LADA can initially be controlled by lifestyle change and oral hypoglycemic agents, and may therefore masquerade as type 2 diabetes. However, in comparison to the typical patient with type 2 diabetes, LADA patients are leaner and

progress much more rapidly to requiring insulin. Importantly, markers of autoimmunity (most commonly anti-GAD antibodies) are present, and therefore LADA falls within type 1 autoimmune diabetes.

- *Idiopathic:* There are some forms of type 1 diabetes which have no known etiology, and no evidence of autoimmunity. Some of these patients have permanent insulinopenia and are prone to ketoacidosis [10]. This form is more common among individuals of African and Asian origin [11].

Type 2 process

Type 2 diabetes is the commonest form of diabetes and is characterized by disorders of insulin resistance and insulin secretion, either of which may be the predominant feature. Both are usually present at the time when diabetes is clinically manifest. Insulin levels may be normal or even elevated at the time when diabetes is diagnosed. However, in the setting of insulin resistance, these levels are inadequate to maintain normoglycemia. This relative insulin deficiency is what differentiates diabetic insulin-resistant individuals from normoglycemic insulin-resistant individuals. Indeed, it is noteworthy that, to date, the majority of the genes that have been associated with type 2 diabetes are related to insulin secretion, and not to insulin resistance [12].

At least initially, and often throughout their lifetime, these individuals do not need insulin treatment to survive [13]. Type 2 diabetes is frequently asymptomatic and undiagnosed for many years because the hyperglycemia is often not severe enough to provoke noticeable symptoms [14]. Nevertheless, such patients are at increased risk of developing macrovascular and microvascular complications. Type 2 diabetes is a very heterogeneous disorder and there are certainly many different causes of this form of diabetes. However, it is likely that the number of patients placed in this category will decrease in the future as identification of specific pathogenic processes and genetic defects permit better differentiation and a more definitive classification. Although the specific etiologies of type 2 diabetes are not known, autoimmune destruction of the pancreas does not occur and patients do not have any of the other specific causes of diabetes listed in Table 1.2.

Most patients with the type 2 process of diabetes are overweight or obese, and obesity itself causes insulin resistance. Many of those not obese by traditional criteria, for example body mass index, may have an increased percentage of body fat distributed predominantly in the abdominal region [13]. Ketoacidosis seldom occurs in type 2 diabetes and when seen, it usually arises in association with the stress of another illness such as infection. Ketosis-prone atypical diabetes, also referred to as ketosis-prone type 2 diabetes is characterized by presentation with severe hyperglycemia and ketoacidosis requiring immediate insulin therapy [15]. More than 50% of these individuals will revert to an insulin-free near-normoglycemia

within weeks or months with multiorgan insulin resistance not dissimilar to type 2 diabetes [16]. This condition is commonly found in sub-Saharan Africa and African migrants and is referred to as "Flatbush diabetes"[17].

The risk of developing type 2 diabetes increases with age, obesity, and lack of physical activity. It occurs more frequently in women with prior GDM, in those with hypertension or dyslipidemia, and its frequency varies between different ethnic subgroups [7]. Type 2 diabetes is often associated with strong familial, likely genetic, predisposition but the genetics of type 2 diabetes are quite complex and not clearly defined [18]. Some patients who present a clinical picture consistent with type 2 diabetes have been shown to have antibodies similar to those found in type 1 diabetes.

Although diagnosis in most patients with type 2 diabetes is made in adult years, the disease is now increasingly seen in adolescents and even children, especially in a background of high obesity prevalence. At presentation, ketosis or even ketoacidosis, may occur in this younger age group and insulin is often required in the initial management. However, once the acute metabolic disturbance is rectified, insulin can often be withdrawn, and glycemic control achieved with lifestyle measures and oral pharmacotherapy.

Other specific types

The other specific types of diabetes are less common and can be broadly classed as genetic, exocrine pancreatic, endocrine, and drug-induced causes [7]. A more comprehensive breakdown is provided in Table 1.2 and the more common types are discussed briefly later.

Classification of genetic disorders

With ongoing advances in the study of molecular genetics, there has been considerable progress in the identification of specific subtypes of diabetes of genetic origin. Through this work, it has been shown that the clinical subgroups are heterogeneous and there has been recognition of several novel, genetic-based syndromes associated with diabetes. The progress in our ability to examine genes to arrive at a diabetes diagnosis has improved treatment for these patients [19] and thus genetic diagnosis has become a key part of clinical management in many countries.

Genetic defects of β-cell function

The diabetic state may be associated with monogenic defects in β-cell function. These forms are characterized by onset of mild hyperglycemia during childhood or early adulthood, and include maturity-onset diabetes of the young (MODY), permanent neonatal diabetes (PNDM), transient neonatal diabetes (TNDM), and many other insulin-deficient syndromes

with a myriad of other clinical features [7]. The most well characterized of these is MODY. MODY is inherited in an autosomal dominant pattern and typically presents before the age of 25 years. While the condition results from β-cell dysfunction, it is not always insulin dependent. Molecular genetic testing can define a diagnosis in 1–2% of all diabetic patients with monogenic diabetes. Advances in this field have led to the identification of the genes associated with many clinically identified subgroups of diabetes and explained clinical heterogeneity in conditions defined by age of diagnosis, for example neonatal diabetes and MODY. Molecular genetic tests are now available to help define the diagnosis, and importantly alter prognosis and optimize treatment of children, young adults and their families with diabetes.

Several mutations associated with MODY have been identified to date, of which the most common genetic subtypes are: GCK MODY, HNF1A MODY, HNF4A MODY, and IPF1 MODY [19]. These are listed in Table 1.2. Among these subtypes, the HNF1A MODY subtype is the most common and results in a progressive and marked hyperglycemia with a high risk of microvascular and macrovascular complications [20], but these patients respond well to sulfonylureas [21]. Subtype HNF4A is similar to HNF1A but patients have marked macrosomia and transient neonatal hypoglycemia [22]. The other subtype, GCK MODY, is a milder form of diabetes, characterized by a mild fasting hyperglycemia that is generally lifelong with little deterioration with age and does not requirement treatment [23,24].

In children less than 6 months of age, diabetes is more likely to be monogenic than autoimmune type 1 diabetes [25]. However, in approximately 50% of these infants, the diabetes is transient (TNDM) [24]. Further to the specific genetic types mentioned here, there are also many subtypes of neonatal diabetes which present as a result of multisystem clinical syndromes [26]. For example, Wolfram syndrome, also referred to as DIDMOAD, is inherited by autosomal recessive trait, is a monogenic multisystem syndrome, and is characterized by marked β-cell dysfunction [27].

Point mutations in mitochondrial DNA have been found to be associated with diabetes and sensori-neural deafness [28] and lead to a condition known as maternally inherited diabetes and deafness (MIDD). Genetic abnormalities that result in the inability to convert proinsulin to insulin have been identified in a few families. Usually such traits are inherited in an autosomal dominant pattern [29] and the resultant carbohydrate intolerance is mild.

Genetic defects in insulin action

Genetic defects in insulin action are rare, and the associated metabolic abnormalities may range from hyperinsulinemia and modest hyperglycemia to severe symptomatic diabetes resulting in death [30]. Acanthosis nigricans may be present in some of these individuals. This syndrome was termed type A insulin resistance in the past. In such patients, diabetes only occurs when there is no β-cell response to the insulin resistance.

Two pediatric syndromes that have mutations in the insulin receptor gene with subsequent alterations in insulin receptor function and extreme insulin resistance are called leprechaunism and the Rabson–Mendenhall syndrome [31]. A heterogeneous group of disorders of lipid storage characterized by lipodystrophy, in which insulin resistance is a common feature, has also been described [32].

Diseases of the exocrine pancreas

Pancreatitis, trauma, infection, pancreatic carcinoma, and pancreatectomy are some of the acquired processes of the pancreas that can cause diabetes. Any process that diffusely injures the pancreas may cause diabetes [33]. With the exception of cancer, damage to the pancreas must be extensive for diabetes to occur. However, adenocarcinomas that involve only a small portion of the pancreas have been associated with diabetes. This implies a mechanism other than a simple reduction in β-cell mass [34]. Hemochromatosis will also damage β cells and impair insulin secretion [35]. Fibrocalculous pancreatopathy may be accompanied by abdominal pain radiating to the back and pancreatic calcification on X-ray and ductal dilatation. Pancreatic fibrosis and calcified stones in the exocrine ducts are found at autopsy [36].

Endocrinopathies

Insulin action can be antagonized by several hormones (e.g. growth hormone, cortisol, glucagon, epinephrine). Diseases associated with excess secretion of these hormones can cause diabetes (e.g. acromegaly, Cushing syndrome, glucagonoma and pheochromocytoma) [7]. These forms of hyperglycemia resolve when the hormone excess is removed. Somatostatinoma and aldosteronoma-induced hypokalemia, can cause diabetes at least in part by inhibiting insulin secretion [37]. Hyperglycemia generally resolves following successful removal of the tumor.

Drug-or chemical-induced diabetes

Insulin secretion may be impaired by many drugs. They may not, by themselves, cause diabetes but may precipitate diabetes in persons with insulin resistance [38]. Pancreatic β-cell destruction may occur with the use of certain toxins such as Vacor (a rat poison) [39], pentamidine [40], and some immunosuppressive drugs. Among these β-cell toxic agents, the most commonly used are the immunosuppressive agents of which the calcineurin inhibitors (e.g. tacrolimus and cyclosporin) are the main culprits. While the main action of calcineurin inhibitors in inducing diabetes is by reducing insulin secretion by pancreatic β cells, these drugs may also increase insulin resistance [41]. There is good evidence to suggest that there is greater potential of tacrolimus to induce diabetes compared with cyclosporine [42]. Diabetes induced by these drugs may be permanent due to β-cell destruction, or may only occur while the drug is being taken, with recovery between treatment cycles [42].

Studies involving other immunosuppressive agents such as mycophenolate mofetil and sirolimus are few and results are inconsistent. Clinical studies have shown that daclizumab

Highly active antiviral therapy, e.g. protease inhibitors
Others

seems to have a neutral effect [43]. Patients receiving interferon alpha have been reported to develop diabetes associated with islet cell autoantibodies and, in certain instances, severe insulin deficiency [44].

There are also many drugs and hormones that can impair insulin action. The list shown in Table 1.3 is not all-inclusive, but reflects the more commonly recognized drug-, hormone-, or toxin-induced forms of diabetes and hyperglycemia. Among these, there are several commonly used diabetes-inducing drugs that deserve special mention. These include the HMG CoA reductase agents (statins), glucocortocoid steroids, anti-HIV agents and antipsychotic drugs.

HMG CoA reductase agents

HMG CoA reductase agents (statins) are commonly used drugs which have been purported to cause diabetes. Sattar et al. [45] reported that statin use compared to placebo increased risk of diabetes in a meta-analysis of 13 placebo-controlled trials. Another meta-analysis comparing intensive dose statin use with moderate statin therapy in five trials showed that the risk of developing diabetes was greater at higher statin doses [46]. The mechanism as to how statins cause diabetes is not known, but it has been suggested that these drugs may affect muscle and liver insulin sensitivity resulting in an increased diabetes risk [46]. It has also been suggested that the observed relationship between statins and diabetes is due to confounding as there is a tendency of individuals who take statins to have a high inherent risk of diabetes. Despite the increased risk of diabetes associated with statin use, a risk–benefit analysis has shown the beneficial nature of statins for cardiovascular disease (CVD), which outweighs the risk of diabetes associated with statin use [47].

Antipsychotic agents

There is accumulating evidence supporting an association of certain psychiatric conditions with type 2 diabetes which can be attributed to side-effects of treatment and a high baseline risk of diabetes in this patient group [48]. Diabetes

can be induced by the use of atypical antipsychotics including clozapine, olanzapine, risperidone, quetiapine, ziprasidone, and aripiprazole. These drugs have a direct effect of raising blood glucose and also lead to weight gain, [48] which subsequently may increase blood glucose levels.

Clozapine and olanzapine have been associated with a higher risk of diabetes than other antipsychotic agents in several studies [48]. These drugs have been associated with new-onset diabetes, exacerbation of pre-existing diabetes, and presentations with complications such as ketoacidosis. The data on risperidone and quetiapine in the studies mentioned earlier show inconsistent findings [48].

Atypical antipsychotics may have an independent effect on insulin sensitivity. Studies comparing insulin sensitivity in patients taking clozapine, olanzapine, or risperidone showed that those in clozapine and olanzapine groups had significantly decreased insulin sensitivity compared to risperidone groups. While there is generally less long-term data on aripiprazole and ziprasidone, a comparison of olanzapine and aripiprazole use in schizophrenic patients showed an increase in glucose in the olanzapine group [48].

Anti-HIV agents

Diabetes is fourfold more common in HIV-infected men exposed to highly active antiretroviral therapy (HAART) than HIV-negative men. Although most of the diabetes observed in this group is type 2 there has been a recent report of autoimmune diabetes and the development of anti-GAD antibodies after immune system recovery post HAART therapy [49], which suggests that type 1 diabetes can also arise in this group from treatment.

HAART is based on the use of a class of drugs known as protease inhibitors (PIs) and include atazanavir, darunavir, saquinavir, and ritonavir. PIs have been shown to increase insulin resistance and reduce insulin secretion, by interfering with GLUT-4 mediated glucose transport. PIs interfere with cellular retinoic acid-binding protein type 1 which interacts with peroxisomal proliferator-activated gamma (PPARγ) receptor. Inhibition of PPARγ promotes adipocyte inflammation, release of free fatty acids and insulin resistance [49]. Hyperglycemia resolves in almost all patients when PIs are discontinued [49] and all PIs do not have the same metabolic effects, with some drugs having a worse adverse effect than others.

Apart from HAART, another class of anti-HIV drugs associated with diabetes are the nucleoside analogs (reverse transcriptase inhibitors) (NRTIs) [50] especially when used for long periods of time [51]. The risk of diabetes is highest with stavudine, but the risk is also significant with zidovudine and didanosine. Proposed mechanisms include insulin resistance, lipodystrophy, and mitochondrial dysfunction [51]. It is postulated that PIs confer acute metabolic risks, while NRTIs confer cumulative risks of diabetes in predisposed, exposed persons. The use of both classes of drugs may be additive for diabetes risk [51].

Glucocorticoids

Glucocorticoids are the most common cause of drug-induced diabetes. They are used in the treatment of many medical conditions but are mostly prescribed for their anti-inflammatory effects [52]. They act through multiple pathways at the cellular and molecular levels, suppressing the cascades that would otherwise result in inflammation and promoting pathways that produce anti-inflammatory protein [53]. The mechanism by which glucocorticoids cause diabetes is thought to be mainly via insulin resistance, but there is also some evidence of effects on insulin secretion [54].

The effect of glucocorticoids is mainly on nonfasting glucose rather than fasting glucose levels [52], but there is uncertainty as to whether this reflects a relationship with clock time (perhaps linked to dosing times), or to a predominant effect on postprandial blood glucose levels.

Infections

Certain viruses have been associated with β-cell destruction. Diabetes occurs in some patients with congenital rubella [55]. Coxsackie B, cytomegalovirus, and other viruses (e.g. adenovirus and mumps) have been implicated in inducing diabetes [56–58].

Uncommon but specific forms of immune-mediated diabetes mellitus

Diabetes may be associated with several immunologic diseases with a pathogenesis or etiology different from that which leads to the type 1 diabetes process. Postprandial hyperglycemia of a severity sufficient to fulfill the criteria for diabetes has been reported in rare individuals who spontaneously develop insulin autoantibodies. However, these individuals generally present with symptoms of hypoglycemia rather than hyperglycemia [59]. The "stiff man syndrome" is an autoimmune disorder of the central nervous system, characterized by stiffness of the axial muscles with painful spasms. Affected people usually have high titers of anti-GAD and approximately one third to one half will develop type 1 diabetes [60].

Anti-insulin receptor antibodies can cause diabetes by binding to the insulin receptor thereby reducing the binding of insulin to target tissues [61]. However, these antibodies can also act as an insulin agonist after binding to the receptor and can thereby cause hypoglycemia [62]. Anti-insulin receptor antibodies are occasionally found in patients with systemic lupus erythematosus and other autoimmune diseases [63].

Other genetic syndromes associated with diabetes

Many genetic syndromes are accompanied by an increased incidence of diabetes mellitus. These include the chromosomal abnormalities of Down syndrome, Klinefelter syndrome, and Turner syndrome. These and other similar disorders are listed in Table 1.4.

Table 1.4 Other genetic syndromes sometimes associated with diabetes

Down syndrome
Friedreich's ataxia
Huntington's chorea
Klinefelter syndrome
Lawrence–Moon–Biedl syndrome
Myotonic dystrophy
Porphyria
Prader–Willi syndrome
Turner syndrome
Wolfram syndrome
Others

Diabetes is commonly observed in cystic fibrosis patients. While it shares features of type 1 and type 2 diabetes, cystic fibrosis-related diabetes (CFRD) is a distinct clinical entity. It is primarily caused by insulin insufficiency, although fluctuating levels of insulin resistance related to acute and chronic illness and medications such as bronchodilators and glucocorticoids also play a role [64]. Since blood glucose levels within the IGT range appear to have an adverse effect on lung function, it has been suggested that diagnostic criteria for CFRD should be lower than that for other forms of diabetes, but data are currently inadequate to make this change [64]. CFRD is not associated with atherosclerotic vascular disease, despite the fact that individuals with cystic fibrosis nowadays can have a lifespan well into the 50s and 60s.

There are several distinct clinically defined subgroups of diabetes where an etiology has not yet been defined. In recognition of this, during the most recent WHO consultation, it was recommended that a category of "unclassified" or "nonclassical phenotype" be available.

Diabetes in children and youth

Type 1 diabetes in children and youth is typically characterized by weight loss, polyuria, polydipsia, blurring of vision, very high plasma glucose concentrations, and ketonuria. The diagnosis is usually very clear with high random glucose values, and there is rarely a need to investigate with an oral glucose tolerance text (OGTT). Type 2 diabetes in children is associated with milder symptoms and is often associated with obesity. In these cases, diagnosis is made using any one of OGTT, fasting plasma glucose, or HbA1c, with preference for HbA1c as there is no requirement to fast. However, there is still debate as to the use of the latter in children [65].

Classification of diabetes in youth poses special problems. Although type 1 diabetes remains the most common form of diabetes in youth of European background, type 2 diabetes is increasingly common, especially among adults at particularly high risk of type 2 diabetes. With the increase in obesity over the last 20 years, there has been an increase in type 2 diabetes

in children especially among ethnicities at high risk as well as an increase in the number of children with type 1 who are overweight. Type 2 diabetes may also be present in youth with ketosis or ketoacidosis, which serves only to compound the problem further. While a practical delineation between these may be the use of insulin, it can no longer be assumed that those on insulin are type 1. Other investigations which could provide insight include measurement of C-peptide, characteristic type 1 antibodies, for example anti-GAD antibodies, and the monitoring of endogenous insulin secretion over time [17].

There has also been an increase in the number of children and adolescents with a mixture of the two types of diabetes, that is, subjects who are obese and/or with signs of insulin resistance as well as being positive for markers of autoimmunity to β cells. These cases present a problem under the current classification as they present with an overlapping phenotype of both type 1 and type 2 diabetes and have been referred to as hybrid diabetes, double diabetes, or latent autoimmune diabetes in youth (LADY) [66]. In such children, presentation of double diabetes is similar to LADA in adults. However, unlike LADA, little is known about the prevalence of double diabetes or the prevalence and significance of autoimmune markers in children. In addition, whether autoimmune-positive youth with double diabetes progress more rapidly to insulin dependence than those with type 2 diabetes without is not known. This is particularly important as these children/youth could be at risk for complications associated with β-cell dysfunction, as well as macro- and microvascular complications of type 2 diabetes. It has been suggested that the current classification of diabetes should be revised to include this new phenotype [66].

Another challenge among young people is the possibility of misdiagnosis of monogenic diabetes as type 1 and type 2. As noted previously, monogenic diabetes results from the inheritance of mutation(s) in a single gene that regulates β-cell function or less commonly in genes related to insulin resistance.

The clinical characteristics of a child with monogenic diabetes compared to children and youth with type 1 and type 2 are shown in Table 1.5. Monogenic diabetes should be considered in a child initially diagnosed as type 1 who has been diagnosed at less than 6 months of age, has a family history of diabetes with a parent affected, evidence of endogenous insulin production outside the "honeymoon" phase of diabetes with detectable C-peptide, and the absence of pancreatic islet autoantibodies (measured at diagnosis) [67].

In children with an initial diagnoses of type 2, a diagnosis of monogenic diabetes should be considered in the following circumstances: when the child is not obese or other diabetic family members have weight in the normal range, and the child does not have acanthosis nigricans; when the child is from an ethnic group with a low prevalence of type 2 diabetes and when there is no evidence of insulin resistance with normal fasting C-peptide levels [24,68].

In scenarios when monogenic diabetes is misdiagnosed as type 1 or 2, the afore-mentioned criteria should be considered as a

Table 1.5 Clinical characteristics of type 1 diabetes, type 2 diabetes, and monogenic diabetes in children and adolescents [67]

Characteristic	Type 1	Type 2	Monogenic
Genetics	**Polygenic**	**Polygenic**	**Monogenic**
Age on onset	6 months and older	Usually pubertal (or later)	Often postpubertal except glucokinase and neonatal diabetes
Clinical presentation	Most often acute, rapid	Variable; from slow, mild (often insidious) to severe	Variable (may be incidental in glucokinase)
Autoimmunity	Yes	No	No
Ketosis	Common	Uncommon	Common in neonatal diabetes, rare in other forms
Obesity	Population frequency	Increased frequency	Population frequency
Acanthosis nigricans	No	Yes	No
Frequency (% of all diabetes in young people)	Usually >90%	Most countries <10%, Japan 60–80%	?1–3%
Parents with diabetes	2–4%	80%	90%

whole rather than individually and are not absolute. DNA testing is now also available for diagnosis of monogenic diabetes.

DIAGNOSTIC CRITERIA

Diabetes is characterized by hyperglycemia, and thus diagnostic tests focus on establishing elevated blood glucose levels [69]. A casual blood glucose, fasting glucose or an OGTT of 75 grams may be performed. For children, the oral glucose load is proportional to body weight at 1.75 g per kg body weight. Recently, HbA1c has been added as an acceptable and reliable means of diagnosing diabetes (discussed later). The cutpoints for the diagnosis of diabetes are listed in Table 1.6.

In the absence of symptoms clearly attributable to diabetes, a diagnosis should not be based on a single measurement, but requires results within the diabetes range on two separate days.

The most notable change in diagnostic criteria in recent years is the recommendation by the ADA and WHO to use HbA1c for diagnosis of diabetes. A summary of the evolution of this decision is described in the following section.

Diagnosis of diabetes using HbA1c

HbA1c is a hemoglobin variant primarily composed of glycohemoglobin, which is formed by the nonenzymatic attachment of glucose to hemoglobin [70]. It was first identified in 1968 by Rabar, who noted it was associated with diabetes. By 1980, its clinical utility as a marker of glycemic control had been recognized. By the 1990s, supported by strong evidence from two studies, the Diabetes Control and Complications Trial [71] and the United Kingdom Prospective Diabetes Study [72],

and the development of new high throughput methods and improved coefficients of variation (CV), HbA1c had become the cornerstone marker in the monitoring of diabetes. In more recent years, a US national glycohemoglobin standardization program has been established and the International Federation of Clinical Chemistry (IFCC) has taken the lead to ensure that HbA1c assays are standardized. In 2011, the units of reporting were also changed from percentage points to IFCC mmol/mol. After a period of dual reporting, HbA1c will be reported in mmol/mol in many countries.

With some improvement in the assay and standardization of HbA1c, together with evidence from key trials demonstrating the importance of intensive glycemic control (as reflected by HbA1c levels) in reducing the risk of microvascular complications of diabetes, the move from using glucose for diagnosis to HbA1c had begun to gather support. However, concerns over standardization of the HbA1c assays and over other factors that may affect HbA1c continued to dampen the enthusiasm for use of HbA1c for diagnosis. In the last 10 years, however, several developments have resulted in the incorporation of HbA1c into the diagnostic armamentarium. There has been significant improvement in the assays of HbA1c [73], analysis from eight different studies showed that HbA1c is as strongly related to the presence of diabetic retinopathy as are blood glucose levels [74], and HbA1c is strongly predictive of macrovascular outcomes and mortality [75,76].

The advantages of using HbA1c for diagnosis are clear. Firstly, HbA1c has far less day-to-day biological variation than fasting or 2-hour glucose [77]. Secondly, HbA1c is stable for one week at room temperature after collection while glucose is susceptible to glycolysis despite the use of fluoride oxalate to preserve the sample. Thirdly, unlike glucose measurement, there is no requirement for the patient to fast. Finally, glucose

Table 1.6 Values for diagnosis* of diabetes and other categories of hyperglycemia using glucose [69] and HbA1c

	Glucose concentration (mmol L^{-1})			
	Plasma		Whole blood	
	Venous	Capillary	Venous	Capillary
Diabetes mellitus:				
Fasting	≥7.0	≥7.0	≥6.1	≥6.1
or				
2-h post glucose load	≥11.1	≥12.2	≥10.0	≥11.1
Impaired glucose tolerance:				
Fasting concentration	<7.0	<7.0	<6.1	<6.1
and				
2-h post glucose load	7.8–11.0	8.9–12.1	6.7–9.9	7.8–11.0
Impaired fasting glucose:				
Fasting	6.1–6.9	6.1–6.9	5.6–6.0	5.6–6.0
and (if measured)				
2-h post glucose load	<7.8	<8.9	<6.7	<7.8

Diagnostic cutpoints for pre-diabetes and diabetes using HbA1c	
Diabetes	≥6 5% (48 mmol mol^{-1})
Increased risk (ADA) [5]	5.7–6.5% (38–48 mmol mol^{-1})
High risk (International Expert Committee) [79]	6.0–6.5% (42–48 mmol mol^{-1})

*Note that diabetes can only be diagnosed in an asymptomatic individual when these diagnostic values are confirmed on another day. Ranges of values are inclusive, i.e., 6.1–6.9 means ≥6.1 and <7.0.

levels are also susceptible to modification by short-term lifestyle intervention while HbA1c reflects glycemia over a period of 3 to 4 months.

The major disadvantage of HbA1c is that there are a number of nonglycemic conditions that interfere with the assay. In particular, alterations of red blood cell turnover (e.g. kidney failure, hematinic deficiencies, hemolysis, acute blood loss, pregnancy, and erythropoietin therapy) may affect the relationship between HbA1c and recent glycemia. The other important disadvantage is the need for a laboratory to use an IFCC aligned assay and be part of a standardization program, which may not be possible in developing countries.

Cutpoints of HbA1c have been set using similar methods to those adopted for the setting of blood glucose criteria. Cross-sectional data from 47,364 individuals from 12 countries reported that the threshold for diabetes-specific retinopathy was 6.3% (45 mmol mol^{-1}), with an optimal decision limit of 6.5% [74]. This latter cutpoint has been adopted by the ADA and WHO as an appropriate cutpoint for diabetes.

Although support for the use of HbA1c for diagnosis of diabetes has increased over the years, several questions about its suitability remain. For example, what should be the appropriate HbA1c ranges for pre-diabetes or intermediate glycemia? The ADA suggested that 5.7–6.5% (39–48 mmol mol^{-1}) should be used [5] to indicate intermediate glycemia while the WHO [78]

suggested that levels of HbA1c below 6.5% may indicate intermediate glycemia but were reluctant to indicate a precise lower cutpoint. An international expert committee suggested that those with HbA1c between 6.0–6.5% (42–48 mmol mol^{-1}) could be considered at high risk, and should be targeted for diabetes prevention activities [79].

A further concern about moving from glucose to HbA1c to diagnose diabetes is that we will observe a change in prevalence of diabetes, as an elevated HbA1c does not identify exactly the same individuals as does an elevated blood glucose. It should, however, be noted that a similar discrepancy in individuals identified also applies to diagnosis by fasting glucose compared to diagnosis by 2-hour plasma glucose in the OGTT.

In general, the use of HbA1c for diagnosis of diabetes results in a lower prevalence of diabetes with the magnitude of the difference between blood glucose-based prevalence and HbA1c-based prevalence varying widely between populations [80].

Diagnosis of diabetes using HbA1c is now recommended by both the ADA and WHO as detailed in Table 1.6. As discussed earlier, it is important to ensure that the HbA1c assay used meets stringent quality assurance test and is aligned with the IFCC standardization program. It is also important to ensure that there are no clinical conditions that preclude its accurate measurement.

Table 1.7 Diagnostic criteria for gestational diabetes mellitus [82]

Fasting venous PG	≥5.1 mmol L^{-1}
1-h venous PG	≥10.0 mmol L^{-1}
2-h venous PG	≥8.5 mmol L^{-1}

One or more of these values must be abnormal for the diagnosis of GDM.

Diagnosis of gestational diabetes mellitus

The diagnosis of gestational diabetes mellitus has been traditionally based on glucose tolerance levels measured between 24 and 28 weeks of gestation [7] using an OGTT. These guidelines have been modified due to the evidence from the Hyperglycemia and Adverse Pregnancy Outcome Study (HAPO) [81]. HAPO was a large, prospective, blinded, multinational study showing a strong and continuous relationship of maternal glycemia at 24–28 weeks with neonatal outcomes of increased birth weight and increased cord–blood serum C-peptide levels, and to increased cesarean section delivery rates in the mothers. Based on these data, new GDM guidelines [82] were proposed which have since been adopted internationally. Diagnostic criteria for gestational diabetes are shown in Table 1.7.

OTHER GLUCOSE TOLERANCE CATEGORIES

Impaired glucose regulation (impaired glucose tolerance and impaired fasting glycemia)

Impaired glucose tolerance (IGT) and impaired fasting glycemia (IFG) are categorized as stages in the natural history of disordered carbohydrate metabolism. They occur in all individuals as they progress from normal to diabetes, but since the transition through these states is rapid in type 1 diabetes, they are rarely identified in such individuals. Therefore, nearly all of the literature dealing with IGT and IFG is concerned with issues relating to type 2 diabetes, such as risk of developing type 2 diabetes and CVD.

IFG and IGT represent a metabolic state intermediate between normal glucose homeostasis and diabetes. The pathophysiologic aspects of hyperglycemia of each category are somewhat different. IGT is associated with muscle and liver insulin resistance and thus IGT is often associated with the metabolic or insulin resistance syndrome [7], while IFG is usually related to insulin secretory deficits.

A meta-analysis suggested that there is a positive relationship between IFG/IGT and diabetes which varies across ethnicity and age [83]. This study showed that individuals with combined IGT and IFG had the highest risk of future diabetes. In terms of sensitivity and specificity for the subsequent development

of diabetes, the sensitivity of IFG as originally defined at 6.1 mmol L^{-1} (110 mg dL^{-1}) is less than that of IGT in most populations [84], but the specificity of IFG is greater [85]. IGT is more common than IFG using 6.1 mmol L^{-1} (110 mg dL^{-1}) in most populations but it should be noted that the sensitivity and specificity of both IGT and IFG is entirely dependent on the cutpoints selected, and not on any inherent differences between FPG and 2hPG [86]. If IGT and IFG are defined such that they have similar prevalence to each other, they then have the same predictive values for subsequent diabetes [86]. Further, with the ADA cutpoint of IFG (5.6 mmol L^{-1} or 100 mg dL^{-1} — see later), the sensitivity of IFG is similar to IGT, but the specificity falls.

Thus, neither the risk of developing diabetes nor the sensitivity and specificity for future diabetes seem to differ enough between IGT and IFG to suggest one category is more useful than the other. In reality, in most populations IGT is more prevalent than IFG (if IFG is defined as FPG of 6.1–6.9 mmol L^{-1} (110–125 mg dL^{-1})), and thus it identifies a greater proportion of those who will develop diabetes. Furthermore, although at the lower cutpoint of IFG of FPG 5.6–6.9 mmol L^{-1} (100–125 mg dL^{-1}), the prevalence of IFG approaches that of IGT, the two groups remain limited in their overlap. Relying on only a FPG will not identify the same proportion of individuals at risk compared to undertaking an OGTT.

The relationship between IGT and IFG and CVD is well studied in meta-analyses. In a review of the evidence from 27 studies [87], IFG (at both cutpoints) and IGT were both associated with a significantly increased risk of approximately 20% of CVD.

Diagnosis of IGT and IFG categories has been traditionally made by measuring blood glucose levels, either in the fasting state (for IFG) or during an OGTT (for IGT) (see Table 1.6 for cutpoints). Since individuals with IFG may have diabetes, it is recommended that those who are found to have IFG should have an OGTT to exclude diabetes [7].

Whilst IGT has been part of the classification of glucose intolerance for many years, IFG was only added in 1997, with a lower cutpoint of 6.1 mmol L^{-1} (110 mg dL^{-1}). However, in 2002, the ADA proposed a new cutpoint of IFG of 5.6 mmol L^{-1} (100 mg dL^{-1}), as this maximized the sensitivity and specificity for predicting future diabetes [88]. On review of the same evidence, the WHO decided not to adopt this new cutpoint, as it significantly increased the number of people being labeled as abnormal, but without evidence that so doing would improve outcomes [69].

The purpose of defining other categories of glucose intolerance or prediabetes is to identify a group of the population at increased risk for the development of both diabetes and CVD, so that interventions (lifestyle and pharmacologic) can be applied to reduce these risks. IGT and IFG are considered risk factors for diabetes and CVD.

In summary, longitudinal data show that IFG and IGT are rather similar to each other in their ability to predict future diabetes and CVD. However, since the populations of

IFG and IGT have limited overlap with each other, undertaking the OGTT to identify those with IGT provides the opportunity to identify a greater proportion of the at-risk population.

Normoglycemia

The notion underpinning setting a normal category of glucose is that people with values below the upper limit of normal are at no or only "normal" risk of developing diabetes or its micro- and macrovascular complications [5,7,84,89]. Since the risks of future development of diabetes and CVD are related to blood glucose across most of its spectrum, and well into any normal ranges that have been set, such notions of "normal" blood glucose should be interpreted very cautiously. The actual setting of the cutpoint indicating *normoglycemia* over the years has undergone considerable changes. The early classification in 1985 by US NDDG that was adopted by WHO had set diabetes at a fasting glucose of 7.8 mmol L^{-1} (140 mg dL^{-1}) and those under this threshold were labeled "normoglycemia". In 1997, upon the availability of new data, the ADA, with support from WHO reset the cutpoint of a "normal" fasting plasma glucose from 7.8 mmol L^{-1} (140 mg dL^{-1}) to 6.0 mmol L^{-1} (110 mg dL^{-1}) [5,7,89]. In 2002–2003, the ADA recommended that the cutpoint be 5.5 mmol L^{-1} (100 mg dL^{-1}) [88].

Summary

The classification of diabetes is an evolving process. As the research into diabetes is a continuing and dynamic process and epidemiologic and clinical studies are in progress, there may well be revision and refinement of the classification system. This is especially important given the recent recommendation to use HbA1c to diagnose diabetes and the caveats to its use. As more knowledge emerges about the etiology of cases currently positioned in the type 2 process category, modification and refinement may be necessary.

Epidemiology and risk factors for type 1 diabetes mellitus

Andrea K. Steck and Marian J. Rewers
Barbara Davis Center for Childhood Diabetes, University of Colorado Denver, Aurora, CO, USA

Key points

- The incidence of type 1 diabetes has been increasing progressively over the last half century by 3–5% per year.
- Type 1 diabetes results from a chronic autoimmune destruction of the pancreatic β cells with a preclinical period marked by the presence of autoantibodies to pancreatic β-cell antigens.
- Though genetic markers can identify varying risk, it is only once autoimmunity has begun that a high positive predictive value is achieved.
- Multiple islet autoantibodies are present in the great majority of prediabetics.
- Studies indicate that genetic factors alone cannot explain the etiology of type 1 diabetes.
- Seasonality, increasing incidence and epidemics of type 1 diabetes suggest a critical role of environmental factors, such as infections with certain viruses and effects of early childhood diet.
- In the absence of renal disease, the long-term mortality risk in type 1 diabetes is not increased compared with the general population.

Introduction

Type 1 diabetes (T1DM) is one of the most prevalent severe chronic diseases of childhood, affecting more than 170,000 children in the United States, an increase of 23% since 2001 [1]. In the US, more than 25,000 children are diagnosed annually with 1:200 children and 1:100 adults diagnosed with T1DM during the lifespan [2]. T1DM is the leading cause of end-stage renal disease, blindness, and amputation, and a major cause of cardiovascular disease and premature death in the general population. Annually, in the US, an estimated 70–200 children die at the onset of diabetes [3] with 30% of children who develop diabetes presenting with ketoacidosis. For unknown reasons, the incidence of T1DM has been increasing progressively over the last half century by 3–5% per year [4]. In addition the percentage of children expressing the highest risk HLA genotype (DR3/4-DQ2/8) has dramatically decreased over the past 50 years [5], apparently reflecting increased disease penetrance of lower risk haplotypes. The high incidence, associated severe morbidity, mortality, and associated healthcare expenditures make T1DM a prime target for prevention. Population-based epidemiological studies as well as family studies and clinical trials have provided new insights into the pathogenesis and natural history of T1DM. Such studies are essential for appropriate diagnosis and for evidence-based programs of prevention and treatment.

Prevalence and incidence

The prevalence of T1DM, that is the proportion of people in the population who have the disease at a given point in time, is determined not only by disease incidence but also by case survival, which may vary markedly in populations. The prevalence of β-cell autoimmunity appears to be roughly proportional to the incidence of T1DM in different populations. In contrast, the prevalence of β-cell autoimmunity in first-degree relatives of T1DM persons does not differ a lot between high and low risk countries for T1DM. The prevalence of T1DM in children aged less than 15 years ranges from 0.05 to 0.3% in most European and North American populations [6].

Incidence is the rate at which new cases of disease appear in the population and is usually expressed as the annual number of new cases per 100,000 persons. Incidence of T1DM varies by geographic location, ethnicity, age, gender, and time. The incidence of T1DM is increasing worldwide both in low and high incidence populations (Figure 2.1) [7]. The average annual incidence is the

Incidence /100,000/ yr
in children 0–14 yr

highest in Finland where it has increased to 64 per 100,000 per year in 2005 [8] while the current mean incidence is 18/100,000 person-years in Australia [9].

Geographic location

One of the most striking characteristics of T1DM is the large geographic variability in the incidence [10–13]. The incidence rates of T1DM vary from 0.73/100,000 per year in China [14] to 60/100,000 per year in Finland. A child in Finland is 100 times more likely to develop diabetes than a child in China. A clear difference appears between the Northern and Southern Hemisphere with countries below the equator having a lower incidence; in contrast above the equator the disease is common. The largest intracontinental variation in incidence appears to be in Europe. There are also noticeable within-country variations in incidence rates, which can only be partially explained by racial composition of the population.

The geographic and ethnic variation in T1DM risk may reflect either different pools of susceptibility genes or different prevalence of causative environmental factors or a combination of both.

Race and ethnicity

There are also striking racial differences in T1DM risk within the same population, although they are not as important as the geographic differences. In the United States, non-Hispanic whites are about one and a half times as likely to develop T1DM as African Americans or Hispanics [15,16]. There are similar differences reported in Europe, where France has lower rates than do Britain and Scandinavia.

Interestingly, there is also evidence that migrants from a country with low incidence of T1DM soon have the higher rate incidence of the country where they live; for example South Asian children living in the UK have similar overall rates of T1DM compared to indigenous white children [17]. Genetic factors are unlikely to explain such a rapid change, implying an influence of environmental factors in disease etiology.

Age and gender

T1DM incidence peaks at the ages of 2, 4–6 and 10–14 years, perhaps due to alterations in the pattern of infections or increases in insulin resistance. Few cases of T1DM develop in the first year of life. The main incidence peak occurs at puberty, with females having a pubertal peak about 1 year earlier. There is a decrease in incidence after puberty for both sexes [18]. In Sweden, the age-specific incidence rates vary from 5–20/100,000 person-years in adults aged 15–35 years and decline with age. Several studies indicate a stable or decreasing trend of T1DM among young adults [18], while, in contrast, a study from Italy (lower-risk population) found that the incidence from 1984 to 1996 increased not only in children but also in young adults [19].

In general, males and females have similar risk of T1DM [20]. In lower-risk populations, such as Japan or African Americans, there is a female preponderance, while in high-risk groups, there is a slight male excess [18]. Interestingly, even within Europe, populations with an incidence higher than 20/100,000 (Sardinia, UK, Italy, Finland, Norway) had male excess, whereas those with a lower rate (the Baltic countries, Macedonia, Yugoslavia, Romania) had female excess [21].

Increasing incidence and seasonality

There is evidence for marked variations in the incidence of T1DM over time, both seasonally and annually. In the Northern Hemisphere, the incidence declines during the warm summer months; similarly in the Southern Hemisphere, the seasonal pattern exhibits a decline during the warm months of December and January, implicating a climatic factor. This seasonal pattern appears to occur predominantly in older children [16], suggesting that factors triggering diabetes may be related to school attendance. Most population-based registries have shown increasing T1DM incidence over time [22,23]. Several studies have observed periodic outbreaks superimposed on a steady secular increase in incidence.

While the increase in T1DM incidence has affected all age groups, several studies have reported a particular increase among the youngest children [24]. In the youngest age group (0–4 years) an increase of 11% and 24% per year was reported in, respectively, the UK and Switzerland [25]. On the contrary, some studies show the highest increase in incidence in children 10–14 years old [13].

In the EURODIAB ACE Study Group, representing most European countries and Israel, the rates of increase were 6.3% (4.1–8.5%) for children aged 0–4 years, 3.1% (1.5–4.8%) for 5–9 years, and 2.4% (1.0–3.8%) for 10–14 years [23].

β-Cell autoimmunity and risk factors

Type 1A diabetes results from a chronic autoimmune destruction of the pancreatic β cells, probably initiated by exposure of a genetically susceptible individual to some environmental

agent(s). This preclinical period is marked by the presence of autoantibodies to pancreatic β-cell antigens such as insulin, GAD65 (Glutamic Acid Decarboxylase), ICA512 (called also IA-2) or ZnT8 (Zinc Transporter 8), and precedes the onset of hyperglycemia by a few years. Several prospective studies have reported that these autoantibodies can appear early in childhood and the presence of two or more of these antibodies is highly predictive for the development of diabetes [26]. However, the etiology of the autoimmune process and β-cell destruction is not known. The islet cell antibody (ICA) assay, using immunofluorescence and pancreatic tissue has been notoriously difficult to standardize and has been replaced by a combination of radioassays for autoantibodies to insulin [27], GAD and IA-2. These tests have been shown to be quite sensitive and predictive in relatives of T1DM patients [26] and in the general population. Several prospective cohort studies investigate early genetic and environmental factors contributing to risk of β-cell autoimmunity and progression to diabetes in relatives of patients with T1DM and in a general newborn population [28,29].

Prediction of T1DM during the preclinical period offers opportunities for prevention of T1DM. Prediction at present is based upon genetic, immunologic, and metabolic information (Figure 2.2). Though genetic markers can identify varying risk, it is only once autoimmunity has begun (marked by the presence of multiple autoantibodies to pancreatic β-cell antigens such as insulin, GAD65, IA-2 or ZnT8) that a high positive predictive value (>90%) can be achieved, and multiple autoantibodies are present in the great majority of prediabetics [30,31].

Family history of T1DM

Concordance rates for T1DM in monozygous twins (MZ) with long-term follow-up is greater than 50% [32], compared to 6–10% in dizygous (DZ) twins, which is similar to what is found in non-twin siblings. With long-term (>30 years) follow-up, at least 2/3 of initially discordant MZ twins develop persistent β-cell autoantibodies and/or diabetes.

Among first-degree relatives, siblings are at a higher risk (5–10% risk by age 20) than offspring; offspring of diabetic fathers are at a higher risk (~12%) than offspring of diabetic mothers (~6%) [33]. It is not clear why offspring of diabetic mothers are at lower risk compared to offspring of fathers, with one study reporting that presence of transplacental islet autoantibodies may decrease risk [34]. It is very likely that both environmental factors and genetic susceptibility are essential for development of T1DM, but the environmental factors may be ubiquitous and thus not be a major determinant of which individual develops diabetes given genetic susceptibility.

HLA class II susceptibility genotypes

The estimated risk of developing T1DM for general population children is 1/300 while the risk for children who have the HLA-DR3/4,DQB1*0201,DQB1*0302 genotype is approximately 1:15–1:25 (Table 2.1) [35]. Only 2.4% of the general population carries this genotype compared to 25–40% of T1DM patients. Deschamps and coworkers examined the predictive value of HLA typing in a study of 536 siblings of diabetic probands in France [36]. The risk of T1DM after 8 years, estimated by life table analysis, was 10% for siblings who were HLA identical with the probands, 3–4% for siblings with either DR3 or DR4, and 16% for those with HLA-DR3/DR4 genotype. Recently, there has been evidence for additional susceptibility loci within or linked to the MHC independent of HLA-DR/DQ, such as HLA class I alleles [37,38]. In the DAISY (Diabetes Autoimmunity Study in the Young) cohort, siblings of children with T1DM who have HLA-DR3/DR4-DQB1*0302 and are identical by descent for both HLA haplotypes with their diabetic proband sibling had a 65% risk for developing islet autoantibodies by age 7 years and a 50% risk of developing diabetes by age 10 years [39]. This strongly suggests that additional (non-DR,DQ) MHC-linked genes determine T1DM risk. On the other hand, DAISY general population children with DR3/DR4-DQB1*0302 who lack protective alleles DPB1*0402 and DRB1*0403 have a risk of 20% of activating islet autoimmunity [40]. Only 25% of autoantibody positive new onset children presenting to the Barbara Davis Center for Childhood Diabetes in Denver during this past decade have the HLA-DR3/4 genotype [41].

Table 2.1 Risk, by the age of 20 years, of type 1 diabetes and β-cell autoimmunity in the general population and family members of T1DM patients

Risk Group	Type 1 Diabetes	Pre-Diabetic Autoimmunity
General population		
All HLA genotypes	1:300	1:30–1:100
HLA-DR3/4,DQB1*0302	1:15	1:10 (?)
Family members		
Maternal offspring	1:50	1:15
Paternal offspring	1:15	1:5
Siblings (all)	1:12–1:35	1:5
Monozygotic twins	1:3	1:1 (?)
HLA-identical siblings	1:4	1:2 (?)

	HLA class I	*IA-2, ZnT8*	*OGTT*
	non-HLA genes	*T cell assays*	*HbA1c*
Figure 2.2 Risk factors and prediction tools for type 1 diabetes.

Several HLA haplotypes dominantly protect, including HLA-DQA1*0102,DQB1*0602, DRB1*1401, DQA1*0101, DQB1*0503 and DRB1*0701,DQA1*0201,DQB1*0303 [42]. Too few HLA-DQB1*0602 individuals expressing multiple islet autoantibodies have been studied to know the exact magnitude of protection once autoantibodies are present, but 1% of new-onset patients expressing islet autoantibodies have DQB1*0602 versus 20% of the general US population.

Other genetic factors associated with type 1 diabetes

More than 40 non-HLA susceptibility gene markers have been confirmed [43]. At present, polymorphisms of the insulin gene and *PTPN22* gene contribute most to diabetes risk after HLA alleles [44]. Adding high-risk alleles of these genetic markers to HLA Class II genotyping can increase risk, but even for these loci with odds ratios between 1.7 and 2.0, the effect is small.

Recent studies indicate that specific single nucleotide polymorphisms (e.g. *PTPN22*) [45] of non-MHC genes are associated with dramatic differences in T-cell signaling. For instance, the *PTPN22* allele associated with diabetes risk is associated with decreased T cell-receptor signaling (gain of function). It is known that a subset of individuals without the specific polymorphism have similar phenotypes, and it is possible that, as diabetes-associated lymphocyte phenotypes are defined, they will contribute to disease prediction [46].

Islet autoantibodies

The first large-scale studies of the prediction of T1DM relied upon the detection of cytoplasmic islet cell autoantibodies (ICA) assays based on indirect immunofluorescence. High titer cytoplasmic ICA is most often associated with the presence of multiple islet autoantibodies and therefore a high risk of progression to diabetes [47]. Screening for risk of T1DM now utilizes "biochemical" autoantibody assays for specific islet autoantigens. These include autoantibodies to insulin (IAA), glutamic acid decarboxylase (GAD), IA-2 (ICA512) and most recently ZnT8 [48]. Individuals having a single positive autoantibody (insulin, GAD, IA-2, or ZnT8 autoantibodies) are at low risk for progression to T1DM. Single positive autoantibodies can be a nonreproducible false positive result (e.g. switched sample), transient, or represent the presence of an autoantibody reacting with the specific autoantigen that does not confer increased risk of diabetes (e.g. low affinity insulin autoantibodies) [49]. Individuals expressing two or more positive autoantibodies, especially on multiple tests over time, are at very high risk of progressing to diabetes. This high risk may result from autoimmunity spreading to other autoantigens whose targeting increases destruction or from the high statistical specificity of expression of multiple autoantibodies. The Diabetes Autoantibody Standardization Program (DASP) workshop aims to improve and standardize measurement of autoantibodies associated with T1DM across laboratories [50].

1 Ab+ N = 74	55	26	13	8	3	1
2 Ab+ N = 47	39	19	10	3	1	
3 Ab+ N = 48	33	20	11	6	1	
Figure 2.3 Progression to diabetes in children positive for anti-islet autoantibodies. Ab+, positive antibody(ies). Source: Steck 2011 [52]. Reproduced with permission of American Diabetes Association.

Different islet autoantibodies have been associated with different risks of progression, with IA-2 autoantibodies most often associated with expression of other biochemical autoantibodies and high risk [51]. Of note, insulin autoantibodies are extremely high at the onset of diabetes in young children while usually negative in individuals first presenting with diabetes after age 12. There is a log-linear inverse relationship between the levels of insulin autoantibodies and the age of onset of diabetes [52]. In DAISY, 89% of children who progressed to diabetes expressed ≥2 autoantibodies with cumulative incidence of 74% by age 10 for those expressing three autoantibodies (Figure 2.3). In children expressing ≥2 autoantibodies, there is no significant difference in progression to diabetes between relatives and general population subjects.

Autoantibody screening among relatives

The initial large screening studies found approximately 3% of first-degree relatives to be positive for ICA. With analysis of biochemical autoantibodies, it has become evident that the presence of ICA in the absence of GAD65 or ICA512 autoantibodies is associated with a low risk of progression to diabetes [26,53]. The cumulative risk of developing diabetes within 15 years is only 2.8% for individuals with ICA but without GAD or ICA512 (IA-2) autoantibodies versus 66% for those with ICA and either or both GAD or ICA512 autoantibodies.

As in many studies, in the DAISY study, the incidence of islet autoantibodies is much higher in first-degree relatives, compared to the general population. The risk by age 10 is particularly high in the HLA-DR3/4,DQB1*0302 positive siblings (43%) and offspring (34%) and moderate-risk siblings (19%) [54]. In the DAISY children without a first-degree relative with T1DM, the incidence of persistent islet autoantibodies by the age of 9 years is 10.6%, 5.5% and 3.4% in, respectively, high-, moderate- and average-HLA risk groups. The HLA genotype and having a diabetic relative, but not gender or ethnicity, predict development of islet autoantibodies.

Islet autoantibodies appear early in life. The BABYDIAB, DIPP, and DAISY studies have demonstrated that a significant proportion of first-degree relatives progressing to T1DM before age 15 develop islet autoantibodies before their 2nd birthday [31,55,56]. Although IAA usually appear first, a significant percentage of children followed from birth initially express GAD65 autoantibodies, while IA-2 and ZnT8 autoantibodies usually develop later.

Autoantibody screening in the general population

Islet autoantibody screening studies have included mainly first-degree relatives; however, 90% of T1DM cases occur in individuals with no family history of T1DM. Several ongoing studies have followed children from birth for the development of islet autoantibodies. The two studies with the longest follow-up are the DAISY study from Denver Colorado and the DIPP study in Finland [57]. More recently, the multicenter international TEDDY study (The Environmental Determinants of Diabetes in the Young) [58] has enrolled over 8600 high-risk general population children identified by newborn screening into a prospective follow-up for islet autoantibody measurements from birth.

While the risk of developing islet autoantibodies is 3–4 times higher in relatives than in the general population with the same HLA-DR/DQ genotypes, the persistent presence of islet autoantibodies portends similar high risk of progression to diabetes for both relatives and the general population [52,59]. Higher titer and higher affinity of the autoantibodies as well as presence of autoantibodies to multiple autoantigens predict higher risk of diabetes [60].

Measurement of autoantibodies in adult-onset diabetes

After the age of about 15 years, measuring the incidence of T1DM is complicated by misclassification of some patients as type 2 diabetics. It has been estimated that at least 37% of T1DM is diagnosed after the age of 19 years and 15% after the age of 30 years [61]. New cases of T1DM presenting in adult life tend to have a longer duration of symptoms before diagnosis and higher C-peptide levels remaining at diagnosis compared with those presenting in childhood, suggesting a slower rate of β-cell destruction. However, C-peptide levels in islet autoantibody positive adult diabetic patients are still significantly lower than in those with type 2 diabetes. Assays for GAD65 autoantibodies have been the most useful in identifying latent autoimmune diabetes in adults (LADA).

Between 5 and 10% of patients with a diagnosis of gestational diabetes have positive islet autoantibodies and the great majority progress to T1DM [62]. Among adults diagnosed with type 2 diabetes and participating in the UKPDS, the proportion of patients with ICA and GAD65 decreased with increasing age at diagnosis: from 21% in patients aged 25–34 to 4% in those aged 55–65 for ICA and from 34% to 7% for GAD65 [63]. Most (94%) of patients with ICA and 84% of those with GAD65 required

insulin therapy by 6 years, compared with 14% of those without the antibodies.

Measurement of β-cell function

Direct measurement of the functional mass of islet cells is currently not possible. The first-phase insulin response (FPIR) to intravenous glucose can help predict progression to diabetes among individuals with positive islet autoantibodies [64,65]. The FPIR is usually calculated as the sum of the 1- and 3-min insulin levels measured after glucose is administered intravenously at 0.5 g per kg body weight. Low FPIR has been defined as below the 1st, 5th or 10th percentile of the distribution in nonobese healthy subjects. Subjects from the Joslin family study with FPIR below the first percentile on the first test had a 3-year diabetes-free survival rate of 13% compared with 78% for the group with higher FPIR [66]. The FPIR is severely depressed at the time of detection of islet autoantibodies in many young children. In the DPT-1 study, loss of the FPIR was strongly associated with diabetes [64]; the average time from the fall of FPIR below the 1st percentile to the onset of diabetes was 1.8 years. A recent study from the Belgian registry reported similar results relative to first-phase insulin secretion with hyperglycemic clamps amongst individuals with IA-2 autoantibodies [67].

The oral glucose tolerance test (OGTT), performed in clinical trials of T1DM prevention largely to formalize the diagnosis of clinical diabetes, has long been known to have some value in predicting progression to T1DM among subjects with islet autoantibodies [68]. DPT-1 reported that a risk score based on age, BMI, and OGTT indexes (glucose and C-peptide values), without use of IVGTTs or additional autoantibodies, accurately predicted T1DM in ICA-positive relatives [69]. The likelihood of progression to diabetes increased with mild fasting or post oral glucose-load dysglycemia.

In 1993, Leech and coworkers reported that HbA1c measured by high-performance liquid chromatography may be slightly but significantly higher in nondiabetic ICA-positive teenagers compared to ICA negative controls [70]. More recently, the DAISY study has demonstrated that Hb1Ac steadily increases within the normal range over a few years preceding diabetes onset and may therefore be useful in early detection of T1DM [71]. Among children who have persistent islet autoimmunity, increase in HbA1c predicted increased risk of progression to T1DM, with a hazard ratio of 4.8 for each 0.4% (SD) increase in HbA1c, independent of random glucose and number of autoantibodies.

Recently, increased HbA1c level has been added by the joint American Diabetes Association (ADA), International Diabetes Federation, and European Association for the Study of Diabetes International Expert Committee (IEC) as a diagnostic tool for diabetes with a recommended threshold of 6.5% for diagnosis of diabetes on two tests [72]. This threshold was established based on research conducted in adults with type 2 diabetes. However, studies in adolescents at high risk for T1DM suggest that HbA1c > 6.5% is a specific but not sensitive early indicator for T1DM [73].

Through the Diabetes Complications and Control Trial (DCCT), it has been shown that patients who have sustained production of C-peptide have lower rates of severe hypoglycemia, microalbuminuria, and retinopathy [74,75]. In the Diabetes Prevention Trial-Type 1 (DPT-1), post challenge C-peptide levels begin to decrease appreciably in the 6 months before diagnosis and continue to decrease within 3 months after diagnosis [76]. Recent data from the TrialNet study show a biphasic decline in C-peptide during the first 2 years post diagnosis, with a higher rate of fall during the first year [77].

Environmental factors

Twin [78] and family studies indicate that genetic factors alone cannot explain the etiology of T1DM. Seasonality, increasing incidence and epidemics of T1DM as well as numerous ecological, cross-sectional and retrospective studies suggest a critical role of environmental factors, such as infections with certain viruses (especially enteric infections in early life) and effects of early childhood diet. Natural history studies that follow children at increased risk of T1DM provide the best opportunity to study environmental triggers.

Viruses: Herpes viruses, mumps, rubella, and retroviruses [79] have been implicated. Viral infections appear to initiate autoimmunity and perhaps also precipitate diabetes in subjects with autoimmunity. ICA or IAA have been detected after mumps, rubella, measles, chickenpox, Coxsackie, ECHO-4, and rotavirus [80] infections.

While several viruses have been linked to T1DM, studies have provided the strongest overall evidence for enteroviruses, although results have been somewhat conflicting [81]. In one longitudinal birth cohort study (DAISY), progression from islet autoimmunity to T1DM seemed to increase after an enterovirus infection [82]. In the Finnish type 1 Diabetes Prediction and Prevention (DIPP) study, enteroviral infections are seen more frequently in prediabetic children and prior to the onset of islet autoimmunity, implying a temporal relationship between enterovirus infections and the induction of β-cell autoimmunity [83]. Although several studies report that enteroviruses may play a role in the pathogenesis of T1DM, the evidence that enterovirus infections are associated with initiation or progression of islet autoimmunity is still inconsistent [84].

Effect of childhood infections and daycare exposure: Early infectious exposure may play a role in the development of immunoregulatory mechanisms that protect against diabetes. Social mixing through attendance at daycare in early infancy appears to confer protection against the development of childhood diabetes [85]. Although several other well-designed case-control studies show a statistically significant protective effect of day care exposure on T1DM [86], meta-analysis reveals too much heterogeneity to accept overall synthesis [87].

Improvement in hygiene: Genetic models are unable to explain the apparent temporal changes in the incidence of T1DM [88]. Alternative explanations look at environmental factors and some invoke the congenital rubella model. Briefly, increased hygiene in the Western world has led to a decline in immunity to common infections among women in child-bearing age. These women are more likely to develop viremia during pregnancy resulting in congenital persistent infection of β cells and early onset T1DM in the offspring. This model could explain both the increasing incidence of diabetes and the decreasing age of disease onset.

Routine childhood immunization: Neither type nor quantity or timing of vaccinations, including BCG vaccine, HIB vaccine, diphtheria, tetanus and pertussis vaccine, measles, mumps and rubella vaccine, hepatitis B vaccine, varicella vaccine, or tick-born encephalitis vaccine, have been associated with the development of islet antibodies and diabetes [86,89,90]. At least two studies even showed a possible protective effect of the measles-mumps-rubella vaccine [91].

Perinatal factors: Environmental risk factors may play a role early in life, possibly in utero. Several studies have investigated perinatal determinants for developing T1DM. Offsprings of a T1DM parent have an increased risk of developing diabetes, the risk being higher if the father has diabetes. Although the relation of maternal age and birth order to risk of T1DM is complex, several studies found that maternal age over 35–40 years [92] and/or increasing birth order [93] were associated with an increase in T1DM. There also seems to be a relatively weak but significant association between increasing birth weight and increasing risk of T1DM [94,95], although several other case-control studies have not found any association [96].

Interestingly, several studies suggest that early weight gain and/or rapid linear growth are risk factors for development of not only type 2 but also T1DM in children [97].

Dietary factors: Cow's milk or wheat introduced at weaning trigger insulitis and diabetes in animal models perhaps through a molecular mimicry [98]. Breast-feeding may be viewed as a surrogate for the delay in the introduction of diabetogenic substances present in formula or early childhood diet. Several human studies suggested an association between short duration of breast-feeding and increase in T1DM [99,100], while cohort studies failed to find an association between cow's milk and β-cell autoimmunity [90,101] (Figure 2.4). Interestingly, a study from Finland suggested that current cow's milk consumption was more closely linked to prediabetic autoimmunity and diabetes than infant exposure [102]. To resolve this controversy, a dietary intervention trial to prevent T1DM by a short-term elimination of cow's milk from infant diet (TRIGR) is underway [103].

Concerning the introduction of cereals, the DAISY [104] and the German BabyDiab [105] studies found that early introduction of gluten before the age of 3 months increases the risk of development of β-cell autoimmunity (Figure 2.4). However, delaying gluten exposure until the age of 12 months in the BabyDiet cohort did not substantially reduce the risk for islet autoimmunity in genetically at-risk children [106].
Figure 2.4 Infant diet and risk for islet autoimmunity. DAISY, Diabetes Autoimmunity Study in the Young; DIPP, type 1 Diabetes Prediction and Prevention study; Ω-3 FA, omega-3 fatty acids; vertical blue line: hazard ratio; longitudinal blue line: 95% CI.

Vitamins and dietary supplements: Studies *in vitro* have shown that vitamin D3 is immunosuppressive or immunomodulating and studies in experimental models of autoimmunity have shown vitamin D to be protective [107]. Results from clinical studies have been somewhat conflicting. While a European study reported a protective effect of vitamin D supplementation in infancy against T1DM [108,109], the DAISY cohort study did not show any association between vitamin D intake or 25(OH)D levels throughout childhood with the risk of islet autoimmunity or progression to T1DM [110] (Figure 2.4). On the other hand, maternal intake of vitamin D through food during pregnancy was associated with a protective effect on the appearance of islet autoimmunity in DAISY offspring [111]; however, these findings were not confirmed in a more recent Finnish study (DIPP) [112]. A study in Norway [109] found that cod liver oil taken during pregnancy was associated with reduced risk of T1DM, suggesting that vitamin D and/or the omega-3 fatty acids in the cod liver oil have a protective effect. In the prospective DAISY study, dietary intake of omega-3 fatty acids and the omega-3 fatty acid content of erythrocyte membranes were associated with reduced risk of islet autoimmunity [113] (Figure 2.4). However, neither intake nor membrane levels of omega-3 or omega-6 fatty acids were associated with risk of developing T1DM in those children with islet autoimmunity [114]. A Nutritional Intervention to Prevent T1D (NIP) is currently underway to examine whether nutritional supplements with docosahexaenoic acid (DHA), given during the last trimester of pregnancy and the first few years of life, can prevent development of islet autoantibodies [115].

Gene–environment interaction in clinical type 1 diabetes

T1DM is likely caused by an interactive effect of genetic and environmental factors within a limited age-window. While both the susceptibility genes and the candidate environmental exposures appear to be quite common, the likelihood of these causal components meeting within the susceptibility age-window is low. To investigate the environmental causes of T1DM, the study subjects have to be screened for known susceptibility gene markers so that gene–environment interactions can be accounted for.

Interaction between HLA Class II alleles and viral infection: Susceptibility to diabetogenic enteroviruses in humans appears to be genetically restricted by HLA-DR and DQ alleles [116]. However, the allelic specificity is controversial and may depend on the viral type and epidemicity. In general, the HLA-DR3 allele, present in most patients with T1DM, is associated with viral persistence.

Interaction between HLA Class II alleles and infant diet: Few studies to date have examined a possibility of an interaction between the HLA genes and dietary exposures [117]. The epidemiologic data are limited, but suggest that an early exposure to cow's milk in relatives with HLA-DR3/4,DQB1*0302, DR3/3 or DRx/4,DQB1*0302 is not associated with development of β-cell autoantibodies [101].

Established type 1 diabetes

Clinical onset

In industrialized countries, 20–40% of T1DM patients younger than 20 years present with diabetic ketoacidosis [118]. After adjusting for age, gender, ethnicity, diabetes type, and family history of diabetes, diabetic ketoacidosis at diagnosis was associated with lower family income, less desirable health insurance coverage, and lower parental education [3]. Younger children present with more severe symptoms at diagnosis, because children younger than 7 years old have lost on average 80% of the islets, compared to 60% in those 7–14 years old and 40% in those older than 14 years [119]. Case fatality in industrialized countries ranges between 0.4–0.9% [120]. Both diabetic ketoacidosis and onset death are largely preventable, because most of the patients have typical symptoms of polyuria, polydipsia, and weight loss 2–4 weeks prior to diagnosis. The diagnosis is straightforward in almost all cases, based on the symptoms, random blood glucose over 200 mg dL^{-1} and/or HbA1c >7%.

Traditionally, nearly all children with newly diagnosed T1DM were hospitalized. More recently, an increasing proportion of new-onset children have been managed on an outpatient basis, especially in urban centers with specialized diabetes education and treatment facilities. Hospitalization at onset does not improve short-term outcomes such as re-admission for diabetic ketoacidosis or severe hypoglycemia [118], if adequate family education and follow-up is available on outpatient basis.

Remission (honeymoon period)

Shortly after clinical onset, most T1DM patients experience a transient fall in insulin requirement due to improved β-cell function. Total and partial remissions have been reported in, respectively, 2–12% and 18–62% of young T1DM patients [118]. Older age and less severe initial presentation of T1DM and low or absent ICA or IA-2 [121] have been consistently associated with deeper and longer remission. Evidence relating GAD autoantibodies [121,122], non-Caucasian origin, HLA-DR3 allele, female gender, and family history of T1DM to a less severe presentation, greater frequency of remission, and slower deterioration of insulin secretion is inconclusive. Most studies agree that preserved β-cell function is associated with better glycemic control (lower HbA1c) and preserved α-cell glucagon response to hypoglycemia.

The natural remission is always temporary, ending with a gradual or abrupt increase in exogenous insulin requirements. Destruction of β cells is complete within 3 years of diagnosis in most young children, especially those with the HLA-DR3/4 genotype. It is much slower and often only partial in older patients [123], 15% of whom have still some β-cell function preserved 10 years after diagnosis.

Acute complications

Acute complications of T1DM (diabetic ketoacidosis, hypoglycemia, and infections) are described in detail in other chapters. The risk of hospital admission for acute complication is 30/100 patient-years in the first year of the disease and 20/100 patient-years in the subsequent 3 years [118]. An estimated 26% of the patients have at least one episode of severe hypoglycemia within the initial 4 years of diagnosis. The incidence of severe hypoglycemic episodes varies between 6 and 20 per 100 person-years, and increases with younger age, longer duration of diabetes, intensity of insulin treatment, lower levels of HbA1c, and in older children with presence of underinsurance and psychiatric disorders [118,124]. The incidence of ketoacidosis is about 8 per 100 person-years and increases with age in girls; the risk of ketoacidosis also increases with higher HbA1c, higher reported insulin dose, and in older children with limited access to care due to underinsurance and presence of psychiatric disorders [124]. Interestingly, most of ketoacidosis and/or hypoglycemic episodes occur among 20% of children who have recurrent events.

Morbidity and mortality

Insulin treatment dramatically prolongs survival but it does not cure diabetes. Excess mortality seems to be lowest in Scandinavia, intermediate in the US, and highest in countries where T1DM is rare, for example, Japan, probably due to a combination of the quality of care and access. On the other hand, 40% of the patients survive over 40 years and a half of these have no major complications. Several studies have shown that survival in T1DM has improved over time [125]. The Pittsburgh Epidemiology of Diabetes Complications (EDC) study cohort has recently shown that the life expectancy for those diagnosed 1965–1980 was 15 years greater than participants diagnosed 1950–1964, a difference that persisted regardless of sex or pubertal status at diagnosis [126]. Both the Finnish Diabetic Nephropathy (FinnDiane) study and the Pittsburgh EDC study report that in the absence of renal disease and microalbuminuria, the long-term mortality risk in T1DM is not increased compared with the general population [127].

Age- and sex-specific prevalence of type 2 diabetes in different ethnic groups

Type 2 diabetes mellitus (T2DM) is now taking its place as one of the main threats to human health in the twenty-first century [1]. In 1921, Dr Elliot Joslin was already concerned that according to his count there had been a doubling of diabetes in three decades [2]. The impact of T2DM is increasingly felt around the world, with its prevalence rising dramatically over recent decades. The World Health Organization (WHO) estimated that there were 150 million people aged 20 years and older living with diabetes in 2000, and by 2025, this will have risen to 300 million (Figure 3.1). There will be a 42% increase, from 51 to 72 million, in developed countries and a 170% increase, from 84 to 228 million, in developing countries [3]. The top 10 countries with the highest estimated number of people with diabetes in 2025 are listed in Table 3.1.

Diagnostic criteria for diabetes

In the past two decades there have been several important developments, which have had significant impact on the definition of diabetes and thereby on the assessment of its magnitude. In 1979, the 2-h 75-g oral glucose tolerance test (OGTT) was proposed as a standard test for diagnosis of diabetes by the National Diabetes Data Group (NDDG) [4], and endorsed by WHO in 1980 [5]. In 1985, WHO made a minor modification to the diagnostic criteria [6]. This has created order out of the confusion in the diagnostic criteria for diabetes. Before that enormous variations existed in diagnostic cutoff values for fasting as well as after glucose loading. The glucose load varied between 50 and 100 g or was body weight related. The differences in glucose assay methods, glucose load, and the time after loading made the comparison between different studies difficult. Near-universal adoption of the WHO criteria has had a significant influence on epidemiologic studies of diabetes.

In 1997, a revision of the diagnostic criteria was approved by the American Diabetes Association (ADA) [7] and adopted by WHO Consultation in 1999 [8]. The major changes were lowering the positive cutoff value of fasting venous plasma glucose from 7.8 mmol L^{-1} (140 mg dL^{-1}) to 7.0 mmol L^{-1} (126 mg dL^{-1}). The positive cutoff value for 2-h plasma glucose remained unchanged, that is, 11.1 mmol L^{-1} (200 mg dL^{-1}) and over. For epidemiologic studies and for routine clinical practice, the ADA did not recommend the primary use of OGTT, but WHO Consultation still retained the OGTT as the standard test procedure. The prevalence data assembled in this chapter are estimated mainly according to the WHO 1999 criteria [8], except for those noted otherwise.

Conversion factors for glucose concentrations

Glucose concentration can be measured using different blood specimens such as venous plasma glucose, capillary whole blood glucose, and venous whole blood glucose. The cutoff points for the classification of stages of glucose abnormalities from different specimens are different. Currently, there are no internationally accepted conversion factors for glucose concentrations in the literature. Recently, conversion factors for changing glucose concentrations between different blood samples were developed on the basis of data from a Finnish study and applied them in the DECODE study (Diabetes Epidemiology: Collaborative Analysis of Diagnostic Criteria in Europe) [9–11]. The equations were derived based on 294 matched samples of whole blood (capillary and serum) glucose and plasma glucose concentrations drawn from a standard 75-g OGTT in 74 individuals at 0, 30, 60, and 120 min at the

Figure 3.1 Number of people with diabetes mellitus, 1995–2025. Source: Adapted from King et al. [3].

Table 3.1 Top 10 countries for estimated number of adults with diabetes, 1995 and 2025

Rank	Country	1995 (millions)	Country	2025 (millions)
1	India	19.4	India	57.2
2	China	16.0	China	37.6

Source: Adapted from King et al. [3].

Diabetes and Genetic Epidemiology Unit, National Public Health Institute in Finland. The relationships between glucose concentrations as measured by the different methods used were estimated. The formulas derived are as follows:

Venous plasma glucose (mmol L^{-1})

= 0.558 + 1.119 × whole blood glucose (mmol L^{-1})

Venous plasma glucose (mmol L^{-1})

= 0.102 + 1.066 × capillary blood glucose (mmol L^{-1})

Venous plasma glucose (mmol L^{-1})

= −0.137 + 1.047 × serum glucose (mmol L^{-1})

Age- and sex-specific plasma glucose concentration

The age- and sex-specific mean fasting and 2-h plasma glucose after 75-g glucose load were estimated in general Caucasian populations in Europe, and in Chinese, Japanese, and Indians in Asia, who did not have prior history of diabetes. The participants are included in the DECODE and the DECODA (Diabetes Epidemiology: Collaborative Analysis of Diagnostic Criteria in Asia) studies, the two largest epidemiologic studies for diabetes in Europe and Asia, with a total of 15,606 subjects from Europe [10] and 19,845 subjects from Asia [12]. The data presented here are based on the pooled data from 13 DECODE and the 11 DECODA participating cohorts. A standard OGTT was carried out in all populations, and subjects with prior history of diabetes were not included in the analysis. The plasma glucose concentrations rose with age and reached a peak at 60–69 years of age and then started to decline in Indians but continued to increase after 70 years of age in Europeans (Figure 3.2). In each age group, the mean 2-h plasma glucose was significantly higher for Indians than for Chinese and Japanese, and the same was also true for fasting plasma glucose in most of the age groups (Figure 3.2). The mean fasting and 2-h glucose concentrations did not differ between Chinese and Japanese except at 40–49 years of age where the glucose values were higher in the Japanese. The mean glucose levels were lower in Europeans than in Asians younger than 70 years, whereas they were higher in Europeans than in Asians 70 years or older. The mean glucose levels were similar in Asian men and women. In Europe, the mean fasting glucose concentration was higher in men than in women at 30–69 years of age but after 70 years of age, it was higher in women. The 2-h glucose was higher in women than in men throughout the age range. Two-hour glucose increased more with age than did fasting glucose.

Age- and sex-specific prevalence of diabetes
Europe

The prevalence of diabetes has been estimated by applying the WHO 1999 criteria [8] for 13 European and 11 Asian cohorts participating in the DECODE and the DECODA studies. In Europe, the age-specific prevalence of diabetes rose with age up to 70s and 80s in both men and women [10] (Figure 3.3). In most of the studies, the prevalence was less than 10% in subjects younger than 60 years and between 10 and 20% at 60–79 years of age. They were higher in Malta than in other populations. The prevalence of isolated postload hyperglycemia (2-h glucose ≥11.1 mmol L^{-1} and fasting glucose <7.0 mmol L^{-1}) increased more with age than did isolated fasting hyperglycemia (fasting glucose ≥7.0 mmol L^{-1} and 2-h glucose <11.1 mmol L^{-1}), particularly in women.

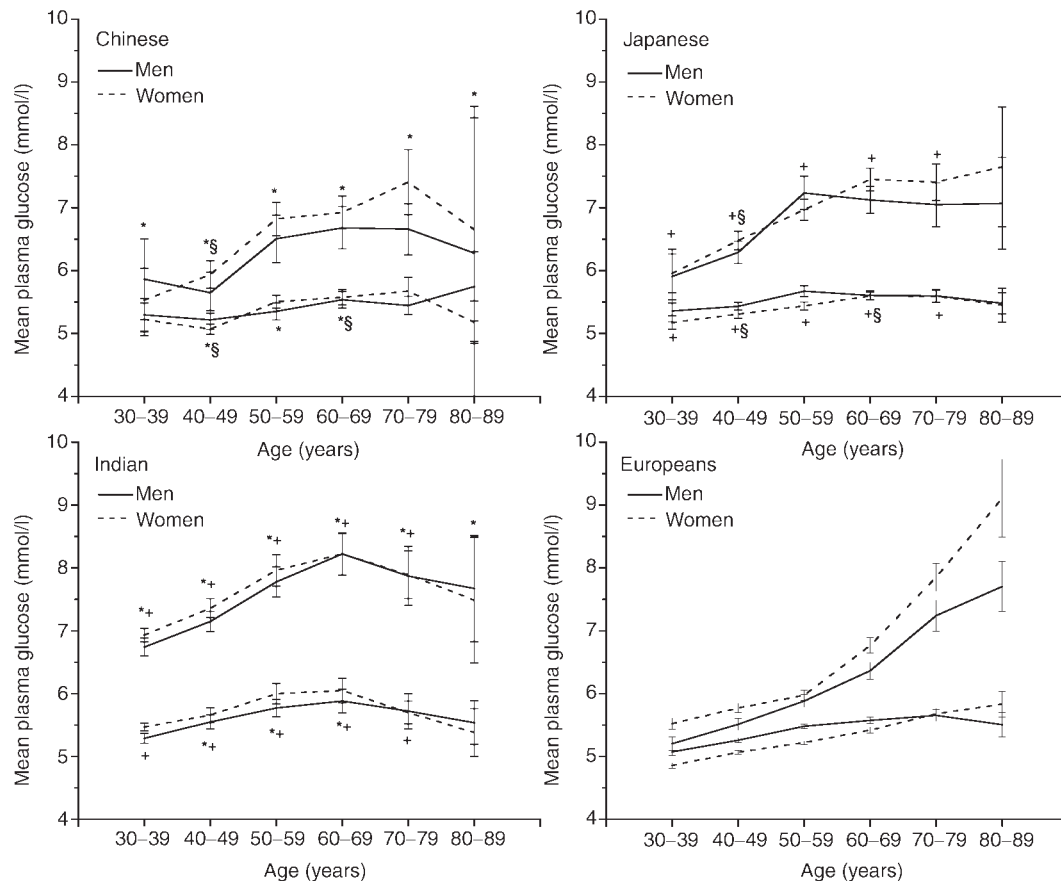
A recent German study using WHO 1999 criteria [8] showed that the prevalence of diabetes in Germany in 2000 was 16.7% in men and 8.6% in women at 55–59 years of age and 23.1% in men and 17.0% in women at 70–74 years of age [13]; that is, rates are within the variation reported for the DECODE study: In the recent Turkish Diabetes Epidemiology Study (TURDEP-II) undertaken in 2010, the prevalence of diabetes was 16.5% and increased with age, reaching a peak of 37.7 % in urban men at 70–74 years and 43.6% in urban women


Figure 3.2 Mean fasting (the two lower lines) and 2-h (the two upper lines) plasma glucose concentrations and their 95% confidence intervals (vertical bars) for the DECODE and the DECODA study populations. * Indians vs. Chinese, +Indians vs. Japanese, §Japanese vs. Chinese, all for p <0.05 for both genders combined. Source: Adapted from the DECODE [10] and the DECODA [12] Study Groups.

at 75–79 years of age [14]. These rates are higher than those reported by an earlier Turkish study in 1997–1998 [15].

Compared with most of the other racial and ethnic groups worldwide, where age- and sex-specific prevalence of diabetes has been reported, Europeans have a moderate to low prevalence of diabetes [10].

United States

In the United States, the prevalence of diabetes varies considerably among different ethnic groups. The prevalence was 1.9 times greater in Latino Americans and 1.6 times in African Americans than in Whites of the same age in the Third National Health and Nutrition Examination Survey (NHANES III) [16]. In NHANES III, where a single fasting plasma glucose $\geq 7.0\,\mathrm{mmol\,L^{-1}}$ was applied for the diagnosis of diabetes, the prevalence of diabetes in US Whites in 1988–1994 was 5.9% in men and 4.8% in women at 40–49 years of age and reached a peak of 19.2% in men and 16.6% in women at 75 years or older [16]. The prevalence of undiagnosed diabetes according to the same fasting glucose criteria at a comparable age range of 40–59 years was higher in US Whites than in most of the female

and in half of the male European populations participating in the DECODE study [10]. The rates were higher in Mexican Americans than in US Whites, and were higher than seen in any of the populations included in the DECODE study.

The Pima Indians have the highest prevalence of diabetes in the world, being 50% at 30–64 years of age, estimated using 2-h postload glucose test alone [17]. The prevalence of diabetes in Native Hawaiians (Polynesian population of Hawaii) in two rural communities was estimated using WHO 1985 criteria [18]. At 30–39 years of age, the prevalence was 6.5% in women and 10.7% in men, reaching a peak of 34.6% in women and 40.0% in men at 70 years or older. Other Native American tribes also have a higher prevalence of diabetes than Caucasoids do.

Central and South America

The age-standardized prevalence of diabetes using 2-h glucose criteria alone was investigated in a Brazilian population in Sao Paulo in 1987 and in a Colombian population in Bogota in 1988–1989 [17]. The prevalences in both populations were similar, around 7% for men and 9% for women. The age-specific prevalence of diabetes in a Mexican population in Mexico City
Figure 3.3 Age- and sex-specific prevalence of diabetes in the DECODE study population. DMF, diabetes by FPG $\geq$7.0 mmol L^{-1} and 2hPG <11.1 mmol L^{-1}; DMP, diabetes by 2hPG $\geq$11.1 mmol L^{-1} and FPG <7.0 mmol L^{-1}; DMF&DMP, Diabetes by FPG $\geq$7.0 mmol L^{-1} and 2hPG $\geq$11.1 mmol L^{-1}. *p < 0.05, **p < 0.01, ***p < 0.001, for the difference between men and women. Source: Adapted from the DECODE Study Group [10].

was 4.2% in men and 3.2% in women at 35–39 years of age and reached 23.1% in men and 41.7% in women at 60–64 years of age [17].

Australia

The Australia Diabetes, Obesity and Lifestyle Study (AusDiab) took place in 1999–2000 applying WHO 1999 criteria mainly in Caucasoids. The prevalence of diabetes increased with age, from 2.7% in men and 2.2% in women at 35–44 years of age to 23.5% and 22.7% at 75 years or older [19]. These rates were higher than those in most of the DECODE populations [10].

Asia and Pacific Islands

Asia The prevalence of diabetes varies markedly among Asian populations. In those participating in the DECODA study, it rises with age up to 70s and 80s in Chinese and Japanese, and in Indian men and women with age up to 60s and then declines [12] (Figure 3.4a,b). The age- and sex-specific prevalence and the peak prevalence of diabetes were higher in cohorts from India and Singapore than in most of the Chinese and Japanese cohorts. In Chinese and Japanese, the prevalence was less than 10% at 30–49 years of age; the peak prevalence was less than 20% in most of the cohorts and none exceeded 30%. In contrast, in India and Singapore the prevalence was over 10% among people aged 40–49 years, and over 30% among those aged 50–69 years for most of the cohorts. The urban Chinese and Japanese had significantly higher prevalences of diabetes than their rural counterparts at 40–69 years of age in men and at 50–79 years of age in women (Figure 3.4). The prevalence of diabetes in Korea was within the range observed in China and Japan [20].

Type 2 diabetes was found at a relatively younger age in Pakistan and the prevalence reached the peak in the age group 55–64 years [21–23]; the prevalence pattern was similar to that in India. In a rural community the prevalence was over 13% at 35–44 years of age, with the highest prevalence of 30% in men at 65–74 years of age [22], indicating diabetes has already become a major health threat in Pakistan as in India.

In the late 1990s, King et al. carried out a series of surveys on diabetes in Uzbekistan and Mongolia using WHO 1985 criteria [6]. In Uzbekistan, the prevalence of T2DM was relatively low in people younger than 45 years, around 1%, and 10–15% at 65 years or older [24]. It was relatively rare in people younger than 45 years, around 1%, and 10–15% at 65 years or older. The prevalence in Mongolia [25] was relatively low with a peak of less than 5% at the age of 65 years or older, comparable to the prevalence reported from China in 1994 [26]. Taking into account the high positive cutoff value of 7.8 mmol L^{-1} for fasting glucose for diabetes in the WHO 1985 criteria, the prevalence reported in these studies would be somewhat higher if the current cutoff value of 7.0 mmol L^{-1} were used. Because different diagnostic criteria have been applied, the results from some of these studies cannot be compared directly with those from the DECODA study [12].

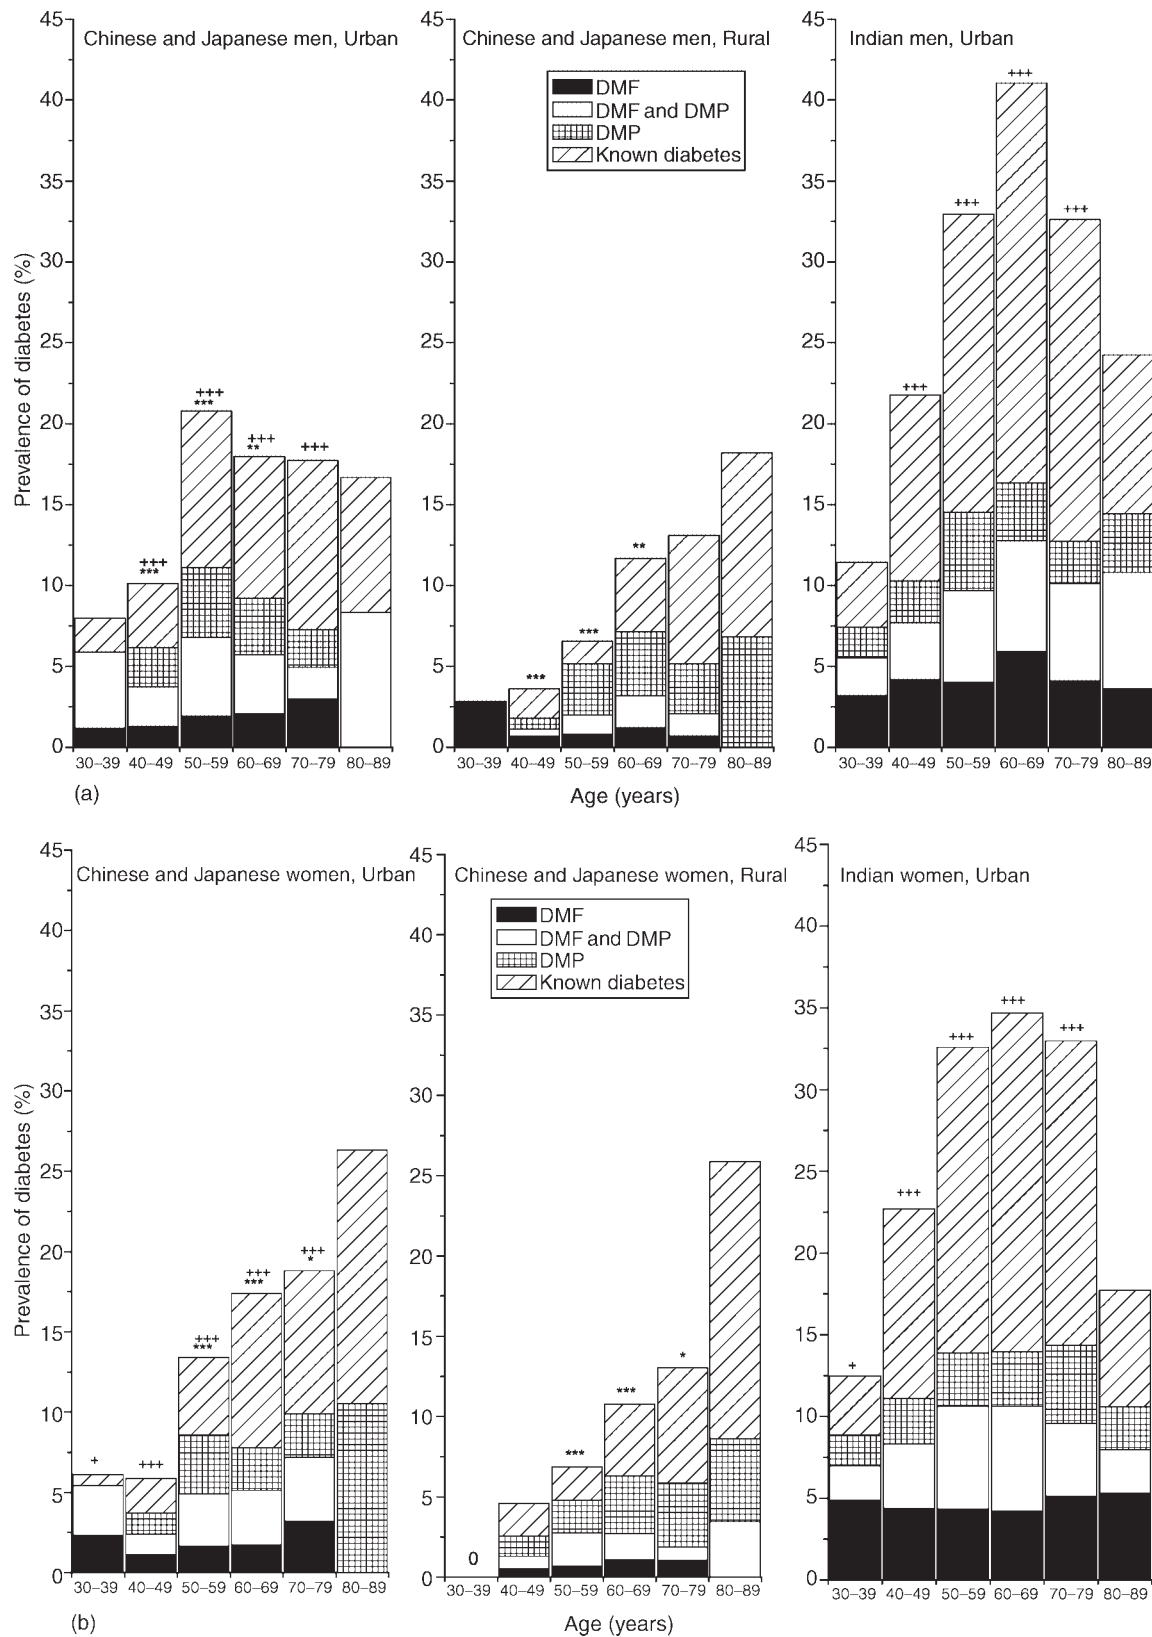
Compared with the European populations included in the DECODE study [10], the age-specific prevalence of diabetes in urban Chinese and Japanese was slightly higher than that in Europeans at 30–69 years of age, but was lower than that in Indians. In the elderly population, however, the peak prevalence was higher in a few European populations than in Indians, such as in Maltese, in Finnish women in Oulu, and in women living in the Canary Islands, Spain. The age at which the peak prevalence


Figure 3.4 Age- and sex-specific prevalence of diabetes in Asia men (a) and women (b) in the DECODA study. DMF, diabetes determined by FPG ≥ 7.0 mmol L^{-1} and 2hPG <11.1 mmol L^{-1}; DMP, diabetes determined by 2hPG ≥ 11.1 mmol L^{-1} and FPG <7.0 mmol L^{-1}; DMF&DMP, diabetes determined by FPG ≥ 7.0 mmol L^{-1} and 2hPG ≥ 11.1 mmol L^{-1}. $^{*}p <0.05,$ $^{**}p <0.01,$ $^{***}p <0.001,$ for the difference between urban and rural Chinese and Japanese; $+ p <0.05, +++ p <0.001,$ for the difference between Chinese and Japanese combined and Indians. Source: Adapted from the DECODA Study Group [12].

of diabetes was reached was similar for Europeans, Chinese, and Japanese (over 70 years), while Indians had their highest prevalence at the age up to 60s and then started to decline. These differences in prevalence in the elderly (women, in particular) are probably due to selective mortality associated with diabetes. The recent survey in China showed a marked increase in the prevalence of T2DM; it was 9.7%, representing an estimated 92.4 million adults in China with diabetes in 2007 [27].

In all Asian populations included in the DECODA study, the prevalence of isolated fasting hyperglycemia (fasting plasma glucose ≥ 7.0 mmol L^{-1} and 2-h plasma glucose <11.1 mmol L^{-1}) did not increase with age (Figure 3.4). The prevalence of isolated 2-h hyperglycemia (2-h plasma glucose ≥ 11.1 mmol L^{-1} and fasting plasma glucose <7.0 mmol L^{-1}) tended to increase with age in Chinese and Japanese but not in Asian Indians [12].

Pacific Islands There are remarkable differences in the prevalence of diabetes among the Melanesia, Micronesian, and Polynesian populations of the Pacific Islands. According to the 2-h postload glucose criteria alone [6], an age- standardized diabetes prevalence of more than 40% was revealed in the Micronesia population of Nauru in the 1980s [28,29]. The prevalence of diabetes in the Melanesia population of Papua New Guinea had been reported close to 0% in highland populations [30], whereas in the urbanized Koki people the age-standardized rate exceeds 40%, approaching that of Nauru [29], exhibiting an extreme urban–rural gradient. Intermediate rates are seen in other Pacific Island populations. In the Polynesia population of the Western Samoa, the crude prevalence rates were 3.4 and 8.7% in rural and urban populations, respectively. By 1991, these rates had risen to 6.5 and 9.0% in two rural communities and to 16% in the urban settings of Apia [31]. A recent study in the Polynesia population of Tonga in 1998–2000 using

2-h OGTT showed that the peak prevalence of diabetes reached 20% in men and 40% in women aged 60 years or older [32].

Middle East

The prevalences of diabetes in Arabian countries, calculated according to the WHO 1985 criteria [6], have been reported to be high [33–35]. It is relatively low before the age of 30 years and starts to increase during the 40s, with the highest in the oldest age group (Figure 3.5). In a rural Palestinian village, in 1996 the prevalence of diabetes was less than 4.0% in people younger than 40 years but increased to 11.0% at 40–49 years of age, with a peak of 21.7% in men and 31.6% in women at 60–65 years of age [35]. The prevalence in Palestine was similar to that in rural Saudi Arabia, but both were lower than that in urban Saudi Arabia [33]. The prevalence of T2DM in 1995–1996 in Kuwait was recalculated using ADA 1997 criteria [7]. It was lower than 3% at age 20–29 years, around 9% at age 30–39 years and higher than 15% at age 40–49 [36]. Diabetes is prevalent in all Arab countries despite the differences in economic status among these countries, indicating that genetic susceptibility and cultural factors may play an important role in the development of the disease.

The age-specific rate ranged from 8% at 40–44 years of age to 25% at 60–64 years of age in Israeli Jews [17].

Africa

In subjects aged 30–64 years, the age-standardized prevalence of diabetes using 2-h glucose alone has been reported to be higher in Hindu and Muslim Indians living in Mauritius [37] and Tanzania [38], around 10% in Tanzania and 13–18% in Mauritius. The age-standardized rate was very low in Bantu in Tanzania, less than 1% in women and 0.9–3.3% in men [39]. The prevalence was 8% in Tunisia [17]. It is interesting to note that the age-standardized prevalence was much higher in

Figure 3.5 Prevalence of diabetes in men and women in three Arabian countries. (For a color version of this figure, please see the color plate section.)

Chinese living in Mauritius than that in Da Qing in China in the mid 1980s [17,37], indicating the importance of impact of the environmental factors.
In Native People: Mapuche and Aymara in Chile and in Siberia in Russian Federation

The native people who still practice their traditional lifestyle and undertake considerable physical activity have extremely low prevalences of diabetes despite their high prevalence of obesity [40,41]. Among Aymara the prevalence of diabetes in 1997 was almost undetectable despite the fact that 13% of the men and 24% of the women had a body mass index (BMI) higher than 30 kg m^{-2} [40]. Similar findings have been reported among native Mapuche [41,42]. The indigenous groups in northern Siberia also showed a very low prevalence, being less than 1% in 1994 [43]. This suggests that a healthy lifestyle with much physical activity provides protection from the development of diabetes. A recent report from Mapuche [41] showed that the prevalence in 1998 was higher than that reported 15 years ago, as was the prevalence of obesity [42], suggesting a possible impact of lifestyle changes on the trends in prevalence of diabetes.

Previously undiagnosed diabetes

The proportion with previously undiagnosed diabetes varies with age. It seems to be highest at 30–39 years of age (70–80%), and lowest in the elderly (around 40%) [10,12]. The only exception was seen in European women where the proportion of undiagnosed diabetic cases was around 40–45% in all age groups. The proportion of undiagnosed diabetes was higher in European men than in European women. In Asians, it was slightly higher in women than in men in the youngest age groups.

Prevalence of impaired glucose tolerance and impaired fasting glycemia in different ethnic groups

A category of nondiabetic fasting hyperglycemia was defined only recently, by the ADA in 1997 [7] and adopted also by WHO in 1999 [8], and named impaired fasting glycemia (IFG). It was introduced by consensus to define impaired glucose homeostasis intermediate between diabetes and normal glucose homeostasis and to be analogous to impaired glucose tolerance (IGT), but without any epidemiologic evidence of possible risks associated with it. Since the introduction of the category of IFG, prospective studies have examined the relationship between IFG and future morbidity and mortality with a comparison to IGT, and shown that the risk of cardiovascular disease (CVD) morbidity and mortality is higher for IGT than for IFG [44–47]. Thus far the data are scarce on the risk of progression to diabetes in subjects with IFG as compared with those with normal fasting glucose or those with IGT. A few studies, which have examined the issue, agree that the risk of developing diabetes is high in subjects with either IFG or IGT and highest in those with both IFG and IGT, as compared with subjects with

normal fasting and normal 2-h glucose [48–52]. At present neither IFG nor IGT is considered a clinical entity, but as a risk category for the future development of diabetes [53]. Each represents a metabolic state intermediate between normal glucose homeostasis and diabetic hyperglycemia, and they were combined and defined formally as impaired glucose regulation (IGR) by WHO Consultation in 1999 [8]. All studies agree that only IGT but not IFG is a risk factor for CVD.

The prevalences of IGT and IFG in Europe and Asia were reported recently by the DECODE and the DECODA Study Groups [8,12].

Europe

The prevalence of IGR rose with age in each study [10] (Figure 3.6). In most of the study populations, the prevalence of IGR was less than 15% at 30–59 years of age and between 15 and 30% after 60 years of age. The prevalence of IGT increased linearly with age, but the prevalence of IFG did not (Figure 3.6). The increase in the prevalence of undiagnosed diabetes and IGR in the elderly population resulted mainly from the proportionately larger increase in postload hyperglycemia than in fasting hyperglycemia.

Asia

The prevalence of IGR rose with age up to the 70s and 80s in most of the study cohorts [12] (Figure 3.7a,b). The increase was graded with aging in Chinese, Japanese, and Singaporean populations, as observed in Europeans, but not in Indians where the prevalence of IGR started to increase by the age of 30–39 years and did not change much with increasing age. The peak prevalences of IGR were not different among different populations, but the age- specific prevalence of IGR was higher in Indians than in Chinese and Japanese at 30–49 years of age for both men and women. In the urban populations the prevalence was higher than in the rural populations aged 40–69 years in men and 50–59 years in women in the Chinese and Japanese populations (Figure 3.7). The difference in the prevalence pattern in different ethnic groups may not be completely explained by living environments and geographic locations, suggesting that genetic differences also play a role.

IGT was more prevalent than IFG in almost all age groups in Asian subjects (Figure 3.7). The prevalence of IGT increases with age whereas IFG does not. This pattern is consistent with that among the European populations [10]. The concordance for IFG and IGT was very poor in all populations, particularly in Asians [10,12,54–56]. The finding that postload hyperglycemia was more prevalent in the elderly in Europe and Asia is consistent with the report from NHANES III [57]. Thus, the prevalence of undiagnosed diabetes and IGR would be underestimated to a large extent, especially in female and elderly populations, if only fasting glucose determination were used. The primary purpose of population-based testing for blood glucose is to detect previously undiagnosed diabetes and IGR in order to apply early intervention to reduce the serious
Figure 3.6 Age- and sex-specific prevalence of impaired glucose regulation (IGR) in the DECODE study populations. Source: Adapted from the DECODE Study Group [10].

diabetic complications and to prevent progression from IGT to diabetes as demonstrated by the recent diabetes prevention trials [58–62].

Sex differences in prevalence of diabetes, IGT, and IFG

The ratio of prevalences of glucose abnormality between men and women has been estimated in many studies, but so far there has been no consistent trend [16,17]. In the DECODE study, we found there is a clear pattern in the prevalence of postload hyperglycemia and the prevalence of fasting hyperglycemia by sex [10]. Undiagnosed diabetes and IFG defined by isolated fasting hyperglycemia was more common in men than in women at 30–69 years of age, whereas the prevalence of isolated postload hyperglycemia was higher in women than in men and was particularly high in the elderly population [10]. In the DECODA study, sex difference was not as clear as in Europe. The prevalence of IFG also seems higher in Chinese and Japanese men than in women, whereas it was higher in Indian women than in men. IGT was more prevalent in Chinese and Japanese women than in men, but such a difference was not observed in Indians [12]. Sex differences in the prevalence of diabetes and IGR depend on how the prevalence was estimated, by fasting or by postload hyperglycemia, on the age distributions, and on the ethnic groups. Asian Indians, who have a very high risk

of diabetes, show abnormalities in fasting glucose values at an earlier age than other populations.

The ratio of IGT to diabetes

The ratio of IGT to diabetes has been reported to decrease as prevalence of diabetes rises [17] and may have some predictive value in determining the stage of a glucose intolerance epidemic within a population [63]. When the ratio is high but the prevalence of diabetes is low, the early stage of a diabetes epidemic may be occurring [17]. The age- and sex-specific ratios of IGR to diabetes according to the newly revised diagnostic criteria for diabetes [8] are shown in Figure 3.8a for Asian and Figure 3.8b for European populations [10,12]. The ratio of IGR to diabetes declined when the prevalence of diabetes increased in both Asian and European populations.

Secular trends in prevalence of type 2 diabetes

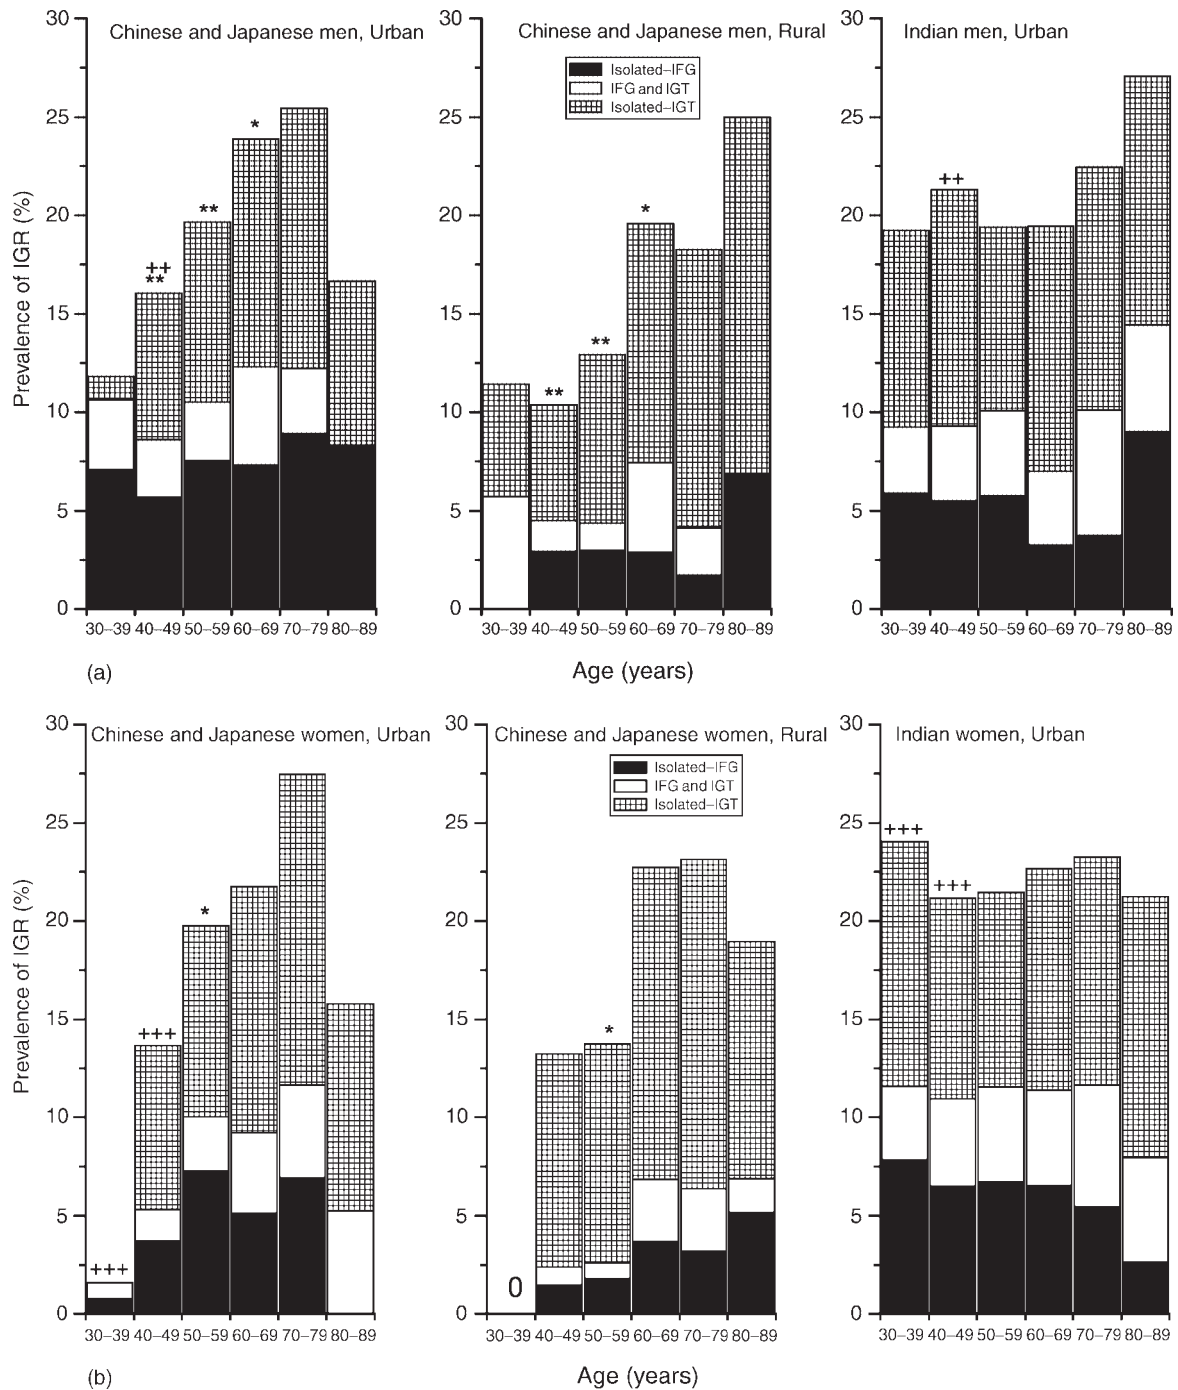
Accumulating evidence shows that the prevalence of diabetes is increasing with time over recent decades. This upward trend has been seen primarily in developing countries [3,64] (Figure 3.1). A series of studies in the southern Indian city of Chennai showed a steady increase in the prevalence of diabetes in the


Figure 3.7 Age- and sex-specific prevalence of impaired glucose regulation in the DECODA study populations in men (a) and women (b). Isolated-IFG, FPG 6.1–6.9 mmol L^{-1} and 2hPG <7.8 mmol L^{-1}; Isolated-IGT, 2hPG 7.8–11.0 mmol L^{-1} and FPG <6.1 mmol L^{-1}; IFG&IGT, FPG 6.1–6.9 mmol L^{-1} and 2hPG 7.8–11.0 mmol L^{-1}. $^{*}p$ <0.05, $^{**}p$ <0.01, $^{***}p$ <0.001, for the difference between urban and rural Chinese and Japanese; $+\,p$ <0.05, $+++\,p$ <0.001, for the difference between Chinese and Japanese combined and Asian Indian populations combined. Indian population. The age-standardized prevalence increased from 8.2% in 1988–1989 [65] to 11.6% in 1994–1995 [66] and reached 13.5% in 2000 [67], a 65% increase within the two decades. During the last two decades a considerable amount of information has been obtained from China. Studies conducted in China between 1980 and 1990 consistently show low diabetes prevalence rates of approximately 1.5% or less, even in urban populations such as in Shanghai in 1980 [68–71]. The prevalence of diabetes in Shanghai in 1980 was close to 1%. In rural Guangdong province it was 0.33% [69]. Studies undertaken in the late 1990s, however, indicate sharply rising prevalence rates

in China [72–74] and the rates estimated at the beginning of the current century show that diabetes in an urban Chinese population in mainland China [75] is already as prevalent as in Hong Kong and Taiwan in the mid 1990s (Figure 3.9) [76–78]. In 2007, the prevalence of T2DM in China was almost 10% indicating a three-fold increase in three decades [27]. It Turkey, the prevalence of T2DM doubled during a 12-year interval from 1998 to 2010 [24]. The prevalence of both diabetes and its microvascular complications in a Pacific Island population (20 years or older) of Western Samoa was examined in 1978 and 1991 [31]. In 1978, the crude prevalence rates were 3.4 and
Figure 3.9 Age-standardized prevalence of type 2 diabetes mellitus in a series of nationwide surveys in China and a recent study in Qingdao city (personal communication with Weiguo Gao).

8.7% in rural and urban populations, respectively. By 1991, these rates had risen to 6.5 and 9.0% in two rural communities and to 16.0% in the urban setting of Apia.

Recent studies indicate that diabetes prevalence continues to increase even in developed countries. According to the data from the US NHANES II and NHANES III surveys, using ADA criteria, the prevalence of T2DM in the US adult population aged 40–74 years of age increased from 8.9% in the period 1976–1980 to 12.3% by 1988–1994. A similar increase was found when WHO criteria were applied (11.4 and 14.3%) [16]. In Australia, the total prevalence of diabetes had increased from 3.4 to 7.2% from 1981 to 1999–2000 and the difference persisted after adjustment for BMI [19] (Figure 3.10). In an adult Norwegian population [79], the crude prevalence of known diabetes in men increased from 2.6% in 1984–1986 to 3.3% in 1995–1997, an increase of 24%, but the increase was not found in women. Over the same time period, an increase
Figure 3.10 Diabetes prevalence (diagnosed and undiagnosed) in Australia according to survey and BMI. Mean values for each BMI category are provided for both surveys. Prevalence data on BMI were adjusted for each population to the 1998 Australia resident population. Source: Adapted from Dunstan et al. [19].

of 86% in the prevalence of obesity defined by BMI $\geq 30\,\mathrm{kg\,m^{-2}}$ was observed in men, which was much higher than the increase of 38% in women. In a Danish study of a 60-year-old cohort over a 22-year period an increase of 58% in men and 21% in women in the prevalence of diabetes was observed, which was fully explained by a concurrent increase in BMI [80]. Rising trends in the prevalence of diabetes and obesity have also been reported in other European countries [81,82]. In addition to the increase in obesity, reduced physical activity resulting from changes in work-related activity and sedentary lifestyle has contributed to the rising trend in T2DM.

Prevalence, which reflects the accumulation of the patients at any given time, can be influenced by many factors such as an increase in the number of new cases and a reduction in the mortality attributed to the disease. There is evidence that mortality in diabetes has declined in men in the United States [83]. Thus, a rise in prevalence could be a result of an improved survival of diabetic subjects. However, studies also show an increasing trend in diabetes incidence due to the increase in obesity and decrease in exercise. Knowler et al. [84] compared the incidence rates over two 10-year time periods, 1965–1975 and 1975–1985, in Arizona Pima Indians, and found that over the 10-year period the incidence rates increased by 50% in most age and sex groups. The San Antonio Heart Study revealed an increasing secular trend in the 7- to 8-year incidence of T2DM occurring from 1987 to 1996 in Mexican American and non-Hispanic Whites [85]. Therefore, both increased incidence and decreased mortality among diabetic subjects have contributed to the increased trend in the prevalence of diabetes.

Type 2 diabetes in children

Prevalence and incidence
Type 2 diabetes was historically a rare occurrence in children but recent studies have reported marked increases in the prevalence of T2DM in children. Type 2 diabetes was first reported in a population-based study in 1979 of American Indians children in Arizona [86]. This American Indian community has one of the highest rates of T2DM in adults and obesity in both adults and children [87]. After 30 years of follow-up in this population, the youngest age of onset of T2DM was 4 years and the prevalence of T2DM in 15–19-year-old children increased from 2.4 to 3.8% in boys and from 2.7 to 5.3% in girls [88]. Data from the Indian Health Service (IHS) in the United States confirmed an increase in the prevalence of diabetes in American Indian populations in the United States, with a 68% increase in the prevalence of diagnosed diabetes in American Indian and Alaska Natives adolescents between the ages of 15 and 19 years between 1990 and 1998. Although these IHS estimates were for all diabetes and not only T2DM, T1DM is very rare in some of these American Indian populations [89,90].

The increase in T2DM is not limited to the American Indians. Very few population-based studies have been conducted in other racial and ethnic groups but results from diabetes

[#]Incident cases.

registries, case reports, and cross-sectional studies from Canada [91], Cincinnati [92], Japan [93–95], Libya [96], Thailand [97], United Kingdom [98–100], India [101], Taiwan [102] and numerous case reports from the United States [103–107] have all indicated a significant increase in the prevalence of T2DM in children, although all these studies did not use a standard method to differentiate between type 1 and type 2 diabetes (see Table 3.2). The incidence of T2DM in African American adolescents in Cincinnati increased 10-fold from 0.7 to 7.2 per 100,000 over a 12-year period [92]. The proportion of T2DM in children diagnosed with diabetes has increased from 2–4% in 1992 to 8–45% in the last decade [108]. The proportion of type 1 to type 2 diabetic children is highly variable according to their different age and racial and ethnic groups (see Table 3.2).

Characteristics and diagnosis

The majority of children with T2DM are non-Caucasian and in one review about 94% of cases were from minority groups [109]. The cause of this increased risk in non-Caucasian groups is unclear but will involve genetic predisposition and cultural and environmental risk factors. African American [110,111] and Hispanic [112] children, for example, have been shown to have higher insulin resistance than do non-Hispanic White children.

The majority of T2DM cases occur in over-weight and obese children and they may have clinical signs of insulin resistance, such as acanthosis nigricans. The prevalence of T2DM in these children is higher in girls who may be two to six times more likely to have T2DM. The mean age of onset is around puberty in most populations.

Cases may present with classical signs and symptoms of diabetes but the disease may have an insidious on-set and may only be detected by opportunistic screening. In a series from a referral center in Cincinnati, 32% of children with T2DM were discovered by opportunistic screening [92]. Therefore, underreporting of cases of T2DM in children may be as common as in adults.

The differentiation of T2DM from T1DM may be difficult in some cases (see Table 3.3). Currently, the mainstay of differentiating diabetes in children is inadequate and includes the use of clinical characteristics such as obesity, severity of onset, use of insulin, age of onset, diabetic ketoacidosis, and family history of diabetes. With the rising prevalence of obesity in children, more T1DM cases are presenting with obesity [113]. In addition, some cases of T2DM may present with diabetic ketoacidosis [114,115]. Diabetes-related autoantibodies that include the glutamic acid decarboxylase (GAD), tyrosine phosphatase-like molecule (IA2), islet cell antibody (ICA), and C-peptide (which is co-secreted with insulin) concentrations are currently being investigated as a means of improving the differentiation of diabetes type in children. The use of diabetes autoantibodies is limited by problems with assay methodology and the transient

nature of some of these autoantibodies in cases of T1DM [116,117]. The use of C-peptide to differentiate the type of diabetes in children is made especially difficult by varying levels of residual β-cell function in type 1 diabetic cases. Current efforts are underway in a CDC (Centers for Disease Control) and NIDDK (National Institute of Diabetes and Digestive and Kidney Diseases) sponsored study, the SEARCH for Diabetes in Youth Study, to develop cutoff points and algorithms that include diabetes autoantibodies and C-peptide concentration which may be used to diagnose and differentiate diabetes in children.

Risk factors

Very few studies have examined the risk factors for T2DM in children. Some of the established risk factors for adult T2DM, discussed in other sections of this chapter, may play a role in the development of T2DM in children. Overweight and obesity are some of the strongest risk factors for insulin resistance and T2DM in adults. The rising prevalence of overweight in children may thus play a role in the risk of T2DM in children. In the United States, the prevalence of overweight in children has increased sharply over the last three decades to 15% in a 1999–2000 survey [118]. Over 20% of Hispanic and African American children are overweight compared to 12% in non-Hispanic White children [119]. This difference in prevalence of obesity may in part explain the higher prevalence of T2DM in ethnic minority children such as American Indians, African Americans, and Hispanics in the United States [88,92,103] and Asian Indians in the United Kingdom [100].

Most cases of T2DM occur around puberty. The reason for this increased risk around puberty is unclear but may be related to the physiologic 30% increase in insulin resistance observed in children as they go through Tanner stages II to IV [120–124]. This physiologic increase in insulin resistance is thought to be related to increased growth hormone production during puberty [121,122] but not related to the increase of sex hormones [121]. In the presence of increased insulin resistance produced by over-weight and physical inactivity the reduction in insulin resistance around puberty may precipitate T2DM in these children especially if they have inadequate compensatory insulin secretion (see Figure 3.11).

Prenatal and early childhood events may also increase the risk of developing T2DM in children. Among siblings from the same nuclear family, the child of a mother who had diabetes during pregnancy has a threefold greater risk of developing early onset diabetes than their sibling who was born before the mother became diabetic [125]. This increased risk is mainly due to exposure to diabetes *in utero* since these siblings share the same environment and a similar probability of inheriting the same genetic composition.

Low birth weight and disproportionate growth *in utero* have been shown to be associated with both T2DM and insulin resistance [126,127]. Breast-feeding is also protective against obesity and T2DM [128–130] especially when sustained for a long durations.

Table 3.3 Challenges in the classification of diabetes in children

| Type 1 diabetes	Type 2 diabetes	Comments
Not overweight	Overweight or obese	Rising obesity means >30% of type 1 are obese
Severe onset	Insidious	Presentations may vary
Weight loss	Some	Presentation may vary
Polyuria	Polyuria	Common to both
Polydipsia	Polydipsia	Common to both
Insulinopenia	No insulinopenia	Not present in all type 1 diabetes in honeymoon phase
Autoantibodies	No Autoantibodies	Usually occur in type 1, absence does not exclude type 1
No insulin resistance	Insulin resistance	Usually occur in type 2
Figure 3.11 Type 2 diabetes, insulin resistance, and puberty in children. (For a color version of this figure, please see the color plate section.)

Complications and comorbid conditions

The development of T2DM in children is alarming. In adults, T2DM is associated with the development of complications such as retinopathy, renal disease, and CVD. Recent reports of T2DM in children suggest that diabetes carries a similar risk for the development of complications in early adulthood. In a study on the development of complications in Pima Indian children with T2DM, the rate of development of nephropathy was as severe in children as in adults over 30 years of follow-up [131]. The rate of development of retinopathy was, however, lower in cases that developed diabetes in childhood. A small series of young adults from the First Nation in Canada who had been diagnosed with T2DM before their 17th birthday were traced and followed up for the prevalence of diabetic complications and adverse outcomes by their 36th birthday. In this small series 9% had died, and 6.3% were already on dialysis and their blood glucose control was poor [132].

At diagnosis, a number of children have comorbid conditions such as dyslipidemia and hypertension both of which are risk factors for CVD [133]. Cardiovascular risk is strongly related to duration of diabetes [134] and T2DM in children will increase their risk to develop CVD later on in life.

The apparent rise in the prevalence of T2DM in childhood is presenting new challenges in the management and classification of diabetes in children. Adolescents are more likely to be noncompliant and may find it more difficult to follow the lifestyle modifications and treatment regimen that would be necessary to control blood glucose [108,135]. Furthermore, very few medications have been approved for use in treating type 2 diabetic children. Insulin and metformin are the only medications currently licensed for treatment of T2DM in children in the United States.

Modifiable risk factors for type 2 diabetes

Obesity

Obesity and weight gain have consistently been shown to be the one of the strongest modifiable risk factors for diabetes [140–142]. The ratio of a person's weight in kilograms divided by the square of their height in meters called the body mass index (BMI) has been used in numerous studies as a surrogate for obesity. In a representative sample of the US population, each unit increase in BMI was associated with a 12% increased risk of T2DM [143]. Compared to people with BMI <22 kg/m^2 those with BMI of 25–27 kg/m^2 had 2.75 times the risk of diabetes, and each kilogram increase in body weight over 10 years was associated with a 4.5% increase in diabetes risk. Numerous studies have found similar results in different populations [144,145], but the magnitude of risk associated with a given BMI may differ across populations. The distribution of weight and weight gain are also important risk factor for diabetes. Central obesity, that is, deposition of fat in the trunk and abdominal areas, has been shown to be a strong risk factors for diabetes. The surrogate measures of central obesity include circumference of waist, waist-to-hip ratio, and waist-to-thigh ratio. More recent technological advances like dual-energy X-ray absorptiometry (DEXA) and magnetic resonance imaging (MRI), and computer tomography have made it possible to measure subcutaneous and intra-abdominal fat. Intra-abdominal fat has been shown to increase the risk of insulin resistance and diabetes in a number of studies in different populations [145–148] and this effect may be independent of the effects of total body obesity [149,150]. Obesity always occurs when energy intake exceeds energy expenditure.

Physical activity

Physical activity has been consistently reported to be inversely related to future risk of diabetes in most populations. Higher levels of physical activity are associated with a lower risk of diabetes in observational studies [151]. Increased physical activity reduces the risk of obesity but its effect on diabetes risk has been shown to be independent of its effect on body weight. Numerous studies have shown that exercise is related to acute and long-term improvements in insulin sensitivity and reduction in insulin concentrations [152,153]. Several epidemiologic studies in diverse populations [154–161] confirm a dose–response relationship between levels of physical activity and diabetes incidence. One study among Finnish men [160] found a strong gradient of diabetes risk associated with intensity of physical activity regardless of duration, but most evidence indicates that the total amount (i.e., number of days or minutes) of physical activity per week is a more important determinant.

Sedentary lifestyle

Sedentary lifestyle has also been shown to be a risk factor for both diabetes and obesity. Prolonged television (TV) watching as a surrogate of a sedentary lifestyle has also been reported to be a risk factor for diabetes [162,163]. Compared to men spending 0–1 h per week watching TV, those spending 2–10 h had 66% higher risk of diabetes, and the risk increased progressively to 187% higher incidence among those spending >40 h per week [162]. In women, every 2 h per day increment in TV watching was associated with a 23% increase in risk of

obesity and 14% increase in risk of diabetes [163]. Furthermore, each 2-h increment in sitting at work was associated with a 5% increase in diabetes risk. It is estimated that a relatively active lifestyle (<10 h per week of TV watching and ≥30 min per day of brisk walking) can prevent 43% of new cases of diabetes [163].

Evidence from intervention studies

Results from the first diabetes prevention trials have clarified the role of physical activity as a risk factor for diabetes. Results from the Malmö trial in Sweden [164], Da Qing trial in China [58], Diabetes Prevention Study (DPS) in Finland [59], and the Diabetes Prevention Program in the Unites States [60] have all shown that moderate physical activity reduces the progression of IGT to diabetes by 30–58%. In these studies moderate physical activity was included in a lifestyle intervention arm of the trials with dietary changes that include reduction in caloric intake and in the percentage of dietary fat and increase in fiber intake (Table 3.4). In most of these studies it is difficult to discern the individual effect of the dietary intervention as it was combined with modifications in physical activity.

Dietary factors

Diet is a phenomenon that is made up of complex interactions between numerous foods and nutrients that are highly correlated and are determined by personal preference, cultural heritage, and socioeconomic factors. Diet is traditionally measured using questionnaires and food diaries. A number of studies have examined the relationship between diabetes and different aspects of diet including absolute intake of nutrients, nutrient intake as a percentage of total energy, dietary patterns, and bioavailability characteristics of foods like glycemic index.

Nutrients and diabetes risk

Dietary fat Animal studies and clinical human studies suggest several plausible mechanisms relating diet to the etiology of T2DM. High-fat diets have been associated with obesity [165], increased body fat for a given weight [166], and altered fat distribution [166]. Furthermore, alterations in cell membrane composition induced by the composition of dietary fat could alter membrane fluidity and/or insulin-mediated signal transduction as well as subsequent insulin action [167].

The results from epidemiologic studies on the relationship of total fat and T2DM have been controversial. In general, most of the migrant [168,169] and retrospective [170,171] studies show a positive relationship between high-fat, low-carbohydrate diets and T2DM, whereas results from prospective studies from different populations have been mixed [172–174] and not as consistent.

The effect of different subtypes of fat such as saturated, polyunsaturated, monounsaturated fat [175,176] and ω-3 fatty acids [177–179] on diabetes risk has also been investigated. An extensive review [180] concluded that while neither total fat nor total carbohydrate as proportions of total energy play a major part in the development of T2DM, specific types of fat and carbohydrate are important. For example, they concluded that (1) higher intake of polyunsaturated fat and long-chain *n*-3 fatty acids (fish oil) may be beneficial, and (2) higher intake of saturated fat and *trans*-fatty acids may be deleterious.

Table 3.4 Lifestyle changes in the primary prevention of type 2 diabetes mellitus

Study	Population	Age (years)	Interventions	Results	Comments
Malmö [164]	181 Swedish men with IGT	47–49	Diet, physical activity, and training	50% with IGT reverted to normal; blood sugars normalized in 50% with diabetes	6-year follow-up; participants were not randomized
Da Qing [58]	577 Chinese men and women with IGT	>25 (mean age 44.9)	Diet only, exercise only, and diet + exercise	Diet only: 31% ↓ in diabetes risk; exercise only: 46% ↓; diet + exercise 42% ↓	6-year follow-up; randomization by clinic
Diabetes Prevention Study (DPS) [59]	522 overweight Finnish men and women with IGT	Middle age (mean age 55)	Increased physical activity, increased fiber intake, and reduced fat intake	58% decrease in diabetes risk	3.2-year follow-up
DPP [60]	3324 overweight US men and women with IGT	Mean age 50.6	Lifestyle (increased physical activity, weight loss, reduced fat intake), and drug (metformin)	Lifestyle 58% ↓ in diabetes risk; metformin 31% ↓	2.8-year follow-up; subjects from several different race/ethnic groups. Lifestyle interventions were effective in all race/ethnic and age groups

Note: IGT = impaired glucose tolerance.

Dietary carbohydrate

The possibility of the risk of diabetes being related to carbohydrate consumption has been frequently raised. This hypothesis was generated because of the stronger, more direct, and more immediate challenge that ingestion of carbohydrate presents to the β cells, compared with in-gestion of proteins or fats. Results from studies on carbohydrate and diabetes risk have, however, been inconclusive [169,181,182]. Other aspects of carbohydrate composition and metabolism including glycemic index and fiber content have also been examined.

Glycemic index The glycemic index [183] of food is a measure of the postprandial excursion of glucose as a result of the ingestion of a fixed amount of food. Foods with high glycemic index cause greater excursions of glucose. The postprandial excursions are dependent on the rate of absorption of glucose, which in turn is dependent on a number of factors including the type of carbohydrate (simple or complex) and the amount of fiber. Food with lower glycemic index has been associated with a lower risk of developing diabetes in some studies [182,184], but others have failed to show any association between the glycemic index of foods and the risk of developing diabetes [185,186].

Fiber intake High-fiber intakes have been related to a reduction in the risk of diabetes in some populations [182,184,187–190]. The mechanism by which high fiber reduces the risk of diabetes is unknown. High-fiber diets usually have a lower glycemic index but some studies that have shown a relationship between fiber intake and diabetes have failed to demonstrate a beneficial effect of the glycemic index of the diet [185]. Thiamine and vegetable protein are found in high concentrations in foods that are rich in fiber and have also been shown to reduce 2-h glucose concentration in women and may explain some of the association between fiber intake and diabetes [191,192].

Vegetable and fruit intake

Higher intakes of vegetables have been shown to be associated with a reduction in the risk of diabetes [172,173,193]. The component of vegetables that confers lower risk has not been clearly identified but may include antioxidants such as carotenoids and tocopherols [194], higher fiber intake, and vitamins [172,195,196]. The effect of fruit consumption on diabetes risk has been inconclusive [173,193].

Dietary patterns and scores

Studies have examined the effect of the whole composition and quality of diet on diabetes risk using various scores and dietary patterns identified by principal component and factor analyses [197,198] on diabetes risk. The results from these studies have shown that a diet that has relatively higher intakes of vegetables and fruits and lower intakes of fat-rich foods has been associated with a reduction in diabetes risk [197,198].

Self-rated dietary patterns can be used to discriminate differences in the nutrient composition in diet. Pima Indians who self-reported a diet more similar to their traditional Pima diet had a lower risk of developing diabetes over a 12-year period [199] when compared to a more Westernized dietary preference. The traditional Pima diet had a higher fiber and lower fat intake when compared to the more Westernized diet. The traditional diets of most indigenous populations have a higher intake of fiber and lower glycemic index [200,201] than the more recent Westernized diets that most of these populations have adopted.

Nontraditional modifiable risk factors for type 2 diabetes

Inflammation

Although insulin resistance and relative insulin deficiency represent the main characteristics of T2DM, the underlying mechanism responsible for these abnormalities remains largely unknown. On the basis of hypothesis that both T2DM and atherosclerosis may generate from a "common soil" [202,203], more recently a growing body of evidence points out that inflammation may constitute the common factor that leads to the development of both these diseases. One of the most used markers of subclinical inflammation is the C-reactive protein (CRP). A number of cross-sectional studies have shown that increased concentrations of CRP are associated with abnormalities characterizing the metabolic syndrome, including obesity, insulin resistance, low HDL cholesterol, and hypertriglyceridemia [204–206]. In addition, prospective studies have demonstrated that high levels of CRP increase the risk of developing T2DM [207–212]. These findings have opened new avenues for understanding the pathogenesis of T2DM and, eventually, for preventing the disease. Indeed, if, as these data have indicated, subclinical inflammation is an important determinant of T2DM, then the use of anti-inflammatory drugs may prevent diabetes. In this regard, it is noteworthy that in patients with T2DM high-dose aspirin reduces insulin resistance and improves glucose tolerance [213].

Smoking

Numerous prospective studies have indicated that smoking is associated with the development of diabetes. In the US Nurses' Health Study, women who smoked at least 25 cigarettes per day compared to those who never smoked had a relative risk of developing diabetes of 1.42, even after controlling for known risk factors [214]. Similar results were shown in men [215]. These findings were confirmed by Will et al. in a prospective study involving over 275,000 men and 434,000 women from the US Cancer Prevention Study [216]. Among those who smoked at least two packs per day at baseline, men had a 45% higher diabetes rate than men who had never smoked; in women the comparable increase was 74%. More important, quitting smoking reduced the rate of diabetes to that of nonsmokers after 5 years in women and after 10 years in men. In support of these findings are cross-sectional data on the association between cigarette smoking and hemoglobin AlC (HbAlC)

from the East Anglian component of the European Prospective Investigation into Cancer (EPIC-Norfolk) [196]. In this study, current smokers had highest mean HbAlC concentrations, lowest levels were observed in never smokers, and intermediate in former smokers. HbAlC levels also correlated in a dose–response manner both with the number of cigarettes smoked per day and with total amount of smoking as measured by pack-years. This association persisted even after adjusting for potential confounders including BMI, waist-to-hip ratio, physical activity, and dietary variables. However, to better assess the role of smoking as a determinant of T2DM we need cohort studies to further confirm that this association exists in different populations.

There is evidence that smoking is associated with insulin resistance [217,218]. In a study by Facchini et al. [217] chronic smokers compared to nonsmokers had significantly higher plasma triglycerides and lower HDL-cholesterol levels and higher insulin concentrations after a 75-g oral glucose challenge. Well-designed clinical studies of the effects of acute and chronic smoking on insulin resistance are needed to elucidate the mechanism by which smoking induces insulin resistance. It is plausible that oxidative stress caused by smoking may induce endothelial dysfunction, resulting in insulin resistance into muscle and liver.

The possibility that smoking may play a causal role in the development of T2DM has important implications for prevention. Both diabetes and smoking are conditions common enough that even a small increase in the risk of diabetes associated with smoking may have an important public health impact.

Physiology of pancreatic function

CHAPTER 4

Development and maintenance of the islet β cell

Teresa L. Mastracci, Raghavendra G. Mirmira and Ryan M. Anderson
Department of Pediatrics, Indiana University School of Medicine, Indianapolis, IN, USA

Key points

- The islets of Langerhans are composed of five hormone-secreting cell types: α cells produce glucagon, β cells produce insulin, δ cells produce somatostatin, PP cells produce pancreatic polypeptide, and ε cells produce ghrelin.

- The pancreas is derived from the merger of distinct buds that are induced dorsally and ventrally from the foregut endoderm by the adjacent mesoderm.

- The extensively branched structure of the mature pancreas is attained by continued growth and remodeling of the primitive tubular epithelium in both dorsal and ventral buds.

- The branching epithelium becomes organized into "tip" and "trunk" domains, within which progenitor cells reside.

- The "secondary transition" is the phase during mid-pancreas development that is marked by the differentiation of exocrine cells and the major wave of islet cells.

- A number of transcription factors expressed broadly in early pancreas development later become restricted to specific endocrine cell types and subsequently acquire additional functions in these cell types.

- The state of β-cell mass and function is a large determinant of glucose and lipid homeostasis.

- β cells exhibit progressively slower rates of turnover as a mammal ages.

Introduction

The discovery of insulin by Banting and Best in the early 1920s marked the beginning of a new era of diabetes research that focused on the study of insulin and the biology of the hormone-producing cells of the pancreas. In the ensuing decades, although much was learned regarding the synthesis, structure, and action of insulin, the developmental origins of insulin-producing β cells remained ambiguous. In the 1970s,

the long-held belief that β cells might arise from the neural crest was refuted by elegant interspecies cell transplantation studies, which demonstrated that radiolabeled quail neural crest cells do not populate pancreatic endocrine tissues in host chick embryos [1]. This seminal finding, and the advent of techniques to manipulate the mouse genome, has resulted in a greater understanding of how the pancreas develops and matures. The lessons from developmental biology have also elicited speculation that maintenance of endocrine cell mass in the adult pancreas follows a similar paradigm, whereby a pool of proliferative progenitor cells differentiates as needed to repopulate the endocrine compartment. It is becoming increasingly recognized that processes that maintain or increase β-cell mass rely on signals distinct from those in the developing pancreas, and therefore the mechanisms of cell specification and maintenance differ depending upon the age of the organism. This chapter reviews the fundamentals of pancreas organogenesis, proceeds with an overview of cytodifferentiation with an emphasis on the β cell, and concludes with a review of β-cell growth and maintenance in the adult pancreas.

Pancreas development

The pancreas is a compound digestive gland, comprised of both exocrine and endocrine components that secrete digestive enzymes and hormones, respectively. The exocrine component makes up approximately 95% of pancreas mass, and consists of acinar cells and duct cells. Acinar cells produce and secrete proteases, lipases, amylases, and nucleases that are necessary for the digestion of nutrients. Duct cells form a tubular network throughout the pancreas, and also secrete mucins and fluids that flush the acinar secretions to the intestine. The mature endocrine component of the pancreas, organized into structures known as the islets of Langerhans, comprises ~2%

of the total organ mass. In the adult, islets of Langerhans are composed primarily of five discrete hormone secreting cell types: α cells produce glucagon, β cells produce insulin and islet amyloid polypeptide, δ cells produce somatostatin, PP cells produce pancreatic polypeptide, and ϵ cells produce ghrelin. β Cells comprise the majority (60–80%) of the cells that make up the islet in vertebrate animals. The progression of pancreas development in vertebrates can be segmented into five major events (summarized in Figure 4.1): (1) induction of definitive endoderm, (2) formation of the primitive gut tube and patterning of endoderm into organ-specific progenitor zones, (3) induction of dorsal and ventral pancreatic buds, (4) outgrowth, branching, and fusion of the pancreatic buds, and (5) cytodifferentiation.

Induction of the definitive endoderm

During early development, pluripotent stem cells in the gastrula stage embryo evolve into the multipotent progenitor cells of the three primary germ layers known as ectoderm, mesoderm, and definitive endoderm. Broadly speaking, mesodermal derivatives provide support and movement, whereas ectodermal derivatives provide for sensation of, and protection from, the environment. The definitive endoderm is the innermost germ layer of metazoan embryos, and its derivatives mediate exchanges with the environment, including nutrient absorption and gas exchange. Definitive endoderm gives rise to the pancreas, liver, intestine and other digestive organs, as well as the thyroid and parathyroid glands and the respiratory tract.

Model systems must be employed to study the mechanisms of development. Considering its evolutionary proximity

to humans and the wealth of sophisticated tools for genetic manipulation, the mouse (*Mus musculus*) is the most pervasively utilized model organism. However, much of what is known about endoderm induction and morphogenesis has been learned through the study of lower vertebrates. Model systems such as the zebrafish (*Danio rerio*), the African clawed frog (*Xenopus laevis*), and the chicken (*Gallus gallus*) each exhibit species-specific experimental advantages (see Table 4.1).

During gastrulation, cells delaminate from the epiblast cell layer, and ingress through a transitory structure called the primitive streak in amniotes (e.g. mammals and birds) or the marginal zone in fish and frog, and emerge as endoderm cells. Although the morphogenetic events of gastrulation vary widely in model organisms, these events are regulated by a conserved set of regulatory molecules. The most fundamental endoderm induction signal is Nodal, a secreted TGFβ-like molecule that is highly conserved in amniotes, amphibians, and fish. Nodal signaling is necessary and sufficient in all vertebrates to trigger a genetic cascade leading to endoderm formation [2]. Nodal is expressed at the site of gastrulation, where it initially generates a transitory mesendodermal precursor cell population. This population is subsequently subdivided into mesoderm and endoderm by the morphogenetic properties of Nodal, with the highest levels of Nodal signaling producing endoderm. Expression of the gene encoding Nodal is initiated in divergent ways depending upon the species. In mice, the gene is induced by WNT signaling at the interface of embryonic and extra-embryonic tissues [3], whereas in zebrafish and frogs it is induced by maternally provided factors that are localized to the site of Nodal induction [4,5]. However, in all vertebrates studied,

Table 4.1 Characteristics of vertebrate model systems

	mouse (*Mus musculus*)	chicken (*Gallus gallus*)	frog (*Xenopus laevis*)	zebrafish (*Danio rerio*)
Genome size	• 3.3×10^9 bp	• 1.1×10^9 bp	• 3.1×19^9 bp	• 1.5×10^9 bp
Gestation time	• 19 days	• 21 days	• ~5 days	• ~5 days
Generation time (egg to egg interval)	• 9–11 weeks	• 18–25 weeks	• 1–2 years	• 10–12 weeks
Lifespan	• 2–3 years	• 1–8 years	• 5–25 years	• 2–4 years
Imaging and embryological manipulations	• Difficult • Fragile embryo	• Simple • Robust embryo • Excellent for micromanipulation	• Simple • Robust embryo • Excellent for micromanipulation	• Intermediate difficulty • Robust embryo
Blastula diameter	• 60–80 μm (small)	• 1–2 mm (large)	• 1–1.3 mm (large)	• ~800 μm (intermediate)
Transgenesis	• Simple transgenesis with common approaches	• Transgenesis is possible, but inefficient • Not widely practiced	• Transgenesis is possible, but inefficient • Not widely practiced	• Simple transgenesis with common approaches
Imaging	• Internal development (*in utero*) • *in vitro* culture of embryos and explants feasible over short time periods. • Opacity of mid and late stage embryos limits deep imaging	• External development (*ex mater*) • Windowing of eggs allows limited live imaging • Opacity of embryos limits deep imaging	• External development (*ex mater*) • Opacity of embryos limits deep imaging	• External development (*ex mater*) • Transparent embryos and fluorescent transgenes facilitate live/time lapse imaging
Forward genetics (find phenotype--> map genotype)	• Mutable with common methods (i.e., ENU, virus) • Growing collection of ENU-induced alleles • Easy mapping of ENU mutations • Relatively time consuming, inefficient, and costly	• Not genetically tractable	• Not genetically tractable • Long egg-to-egg period makes screening time consuming	• Mutable by common methods • Strong history of genetic screens. • Intermediate difficulty in mapping mutations
Reverse genetics (alter genotype--> study phenotype)	• Facile homologous recombination in ES cells • Many targeted alleles and Cre stains available • Antisense morpholinos used rarely	• Antisense morpholino oligos • Viral misexpression of genes	• Antisense morpholino feasible but complicated, due to allotetraploid genome • Produce 100s of synchronous embryos	• Antisense morpholinos • Gene misexpression via DNA or RNA injection • Evolving tools for targeted mutagenesis and homologous recombination • Produce 100s of synchronous embryos

Nodal expression is enhanced by high levels of WNT signaling and maintained by a positive paracrine feedback loop [6]. The targets of Nodal include the *Mix-like* (*Mixl*) family of homeobox genes, the *Foxa* family of forkhead genes, and the high mobility group box gene *Sox17*. Together, these genes comprise an essential transcription factor network that stabilizes the endodermal fate while simultaneously segregating it from mesoderm [7,8].

Patterning of the gut tube into organ domains
All endoderm generated during gastrulation is not equivalent: cells acquire positional identity upon specification, which is dependent upon the time at which the cells are specified. The foregut endoderm is specified first, followed by midgut, then hindgut. As gastrulation concludes, the foregut expresses unique spatial markers, including Hhex, which is directly induced by Nodal, as well as Sox2 and Foxa2. These three transcription factors are essential for the development of foregut organs [2,9,10]. Moreover, the antero-posterior (A-P) patterning of the endoderm is dictated by the release of several signaling molecules from the mesoderm. In addition to Nodal, which induces anterior endoderm at the highest levels of expression and posterior fates at progressively lower levels, a core set of secreted signaling molecules are encountered by migrating cells. Fibroblast growth factors (FGFs), Wingless/Int (WNTs), bone

morphogenetic proteins (BMPs), and retinoic acid (RA) are secreted from a posterior location, serve to suppress anterior fates, and to partition further the gut tube into regions that express genes encoding the crucial transcription factors Pdx1 (intermediate gut region) and Cdx1/2/4 (hindgut region) [3,8]. Moreover, as discussed later, this set of signaling molecules acts iteratively within the pancreatic endoderm throughout development to generate the mature pancreas.

Immediately after formation, the germ layers are arranged as three flat, stacked sheets of cells. The endoderm rapidly transitions to a tubular morphology and becomes enveloped by mesoderm. In amniotes, the morphological transformation begins with the folding together of the lateral edges of the anterior and posterior ends of the sheet to form foregut and hindgut pockets. The lateral edges of the endoderm sheet are then fused together by zipper-like morphogenetic behavior at the ventral midline that progressively seals from the anterior and posterior ends; this process ultimately generates a hollow gut tube. In zebrafish and frogs, the endodermal sheet first forms a solid rod through mass endodermal cell migration toward the midline. This rod later hollows by the mechanism of cavitation, which may involve lumen-directed fluid transport.

The foregut endoderm gives rise to multiple organs, including pancreas, liver, thyroid, and lung. The gut tube becomes subdivided into organ forming regions through reciprocal interactions between the endodermal cells and the adjacent mesenchyme, a process requiring FGF, BMP and RA signaling pathways. Explant studies using uncommitted mouse foregut originally revealed the role of FGF emanating from the septum transversum mesenchyme. Low levels of FGF led to expression of Pdx1 in ventral pancreatic progenitors, intermediate levels led to hepatic fates, whereas the highest levels specified lung and thyroid. Mouse genetic experiments later confirmed this model *in vivo*, and the requirement for FGF is conserved in both zebrafish and frogs [4,5,11]. BMP signals, which also originate from the septum transversum mesenchyme in mammals and from the lateral plate mesoderm in fish, regulate pancreatic specification [6,12]. BMP signals repress pancreatic development from a common pool of progenitors [7,8,13]. RA signaling biases endoderm to more posterior fates, and may have a role in partitioning the expression domains of the genes encoding Pdx1 (Pancreatic and duodenal homeobox 1) and Cdx1 (Caudal type homeobox 1), which are considered master regulators of pancreatic and intestinal fates, respectively. Furthermore, RA may have a direct role in dorsal bud induction, as both mice and zebrafish deficient in RA signaling lack the dorsal pancreas [14,15].

Induction of the dorsal and ventral pancreatic buds

The pancreas is derived from the merger of distinct buds that are induced dorsally and ventrally from the foregut endoderm by the adjacent mesoderm. In all vertebrates, both dorsal and ventral buds are marked by expression of Pdx1 and Ptf1a (Pancreatic transcription factor 1a), two transcription factors essential for proper development of all pancreatic cell types [16]. The ventral bud is specified by low-level FGF signaling from the mesenchyme in the absence of BMP signaling, as described earlier. Dorsal bud fate is specified when FGF2 and Activin signals secreted from the notochord mitigate Sonic Hedgehog (Shh) expression in the dorsal midline of the gut tube [17]. In contrast to the suppressive role of Shh in early pancreatic bud induction, Shh later plays a positive role in the expansion of the pancreatic epithelium and in β-cell function [18]. Additionally, dorsal bud induction requires RA [19] as well as yet unidentified factors secreted from the dorsal aorta. In contrast to amniotes and frogs, dorsal fate specification likely occurs by a divergent mechanism in zebrafish, as Shh has a positive regulatory role in dorsal bud induction [20]. Furthermore, signaling from the dorsal aorta does not appear to have a fundamental role in zebrafish, as *cloche* mutants of zebrafish that lack all vasculature still demonstrate normal bud induction [21].

Pancreatic growth and epithelial branching morphogenesis

The extensively branched structure of the mature pancreas is attained by continued growth and remodeling of the primitive tubular epithelium in both dorsal and ventral buds. Once the buds have been induced, they are critically dependent on interaction with the mesenchyme for continued morphogenesis and cytodifferentiation. Moreover, during tubulogenesis, cytodifferentiation is suppressed, which allows for the expansion of progenitor cell populations, and implies direct communication between the genetic programs controlling each process. Mouse explant studies showed that isolated pancreatic epithelium failed to develop acinar tissues in the absence of mesenchyme, and that secreted factors were likely the mediators of this development [22]. In complementary studies *in vivo*, targeted ablation of pancreatic mesenchyme showed essential roles for epithelial-mesenchymal signaling during both early and late bud morphogenesis [23]. FGF10 from pancreatic mesenchyme supports the proliferative expansion of the epithelium as well as the maintenance of undifferentiated pancreatic progenitor cells via induction of the Notch pathway [24,25]. Additional signals from the mesenchyme instruct the continued development of the buds. For instance, reciprocal EphB signaling between mesenchyme and epithelium is positively required for branching, growth, and cytodifferentiation [26], while unidentified signals from blood vessels restrain these processes [27]. Even as these and other unknown signals regulate its growth, pancreatic mass is ultimately constrained by an intrinsic program established in the pancreatic progenitor domain [28]. Finally, as the foregut grows and elongates, the developing ventral pancreatic tissues rotate along with the gut, and ultimately fuse with the dorsal bud to generate mature pancreatic architecture. Although congenital malformations arising from defective pancreatic bud fusion are relatively common, including annular pancreas and

pancreas divisum, the genetic pathways underlying this process are not well understood [29].

Cytodifferentiation in the developing pancreas

As stated earlier, the early evaginating pancreatic buds are made up of progenitor cells that express Pdx1 and Ptf1a. These early pancreatic progenitor cells will induce the specification of multipotent progenitor cells (MPCs), which direct derivative cell populations toward a particular fate. The early developing pancreatic buds are marked by the appearance of cells with low-level digestive enzyme production and an initial wave of glucagon- and insulin-expressing cell types, a period referred to as the "primary transition" of pancreas formation. The term "secondary transition" is applied to the phase during mid-pancreas development that is marked by the differentiation of exocrine cells and the major wave of islet cell formation [30]. The secondary transition is characterized by a dramatic increase in cells expressing acinar digestive enzymes, as well as a large increase in cells producing endocrine hormones including insulin, glucagon, ghrelin, somatostatin, or pancreatic polypeptide. Preceding this major wave of differentiation, the secondary transition also encompasses the emergence of the MPCs and the establishment of the pre-acinar and bipotent duct/endocrine cell populations from which the differentiated exocrine, and endocrine or duct cells derive, respectively (Figure 4.2).

In recent years, a network of genes has been identified whose products specify the development of the different cell types (see Table 4.2). The importance of these genes has largely been identified by lineage tracing studies and targeted mutations in mouse models, and has led to two important concepts in pancreatic cytodifferentiation. First, the products of many of these genes function in a "cell-autonomous" manner, meaning that their expression level in a given cell type alters the fate and function of that cell. Second, misexpression of specific genes in magnitude or in a spatial (cell- or domain-specific) or temporal (time of development-specific) manner can redirect developing progenitor cells to cell fates they would otherwise not have adopted. With respect to the latter concept, the study of cell-autonomous factors has the potential to identify means through which other cell types might be converted to β cells for the treatment of different forms of diabetes.

Tip versus trunk domains

The stratification of the pancreatic epithelium and the resulting formation of microlumens is an essential morphological change that occurs during the primary transition. The subsequent remodeling of the ductal plexus and branching of the epithelium continues throughout embryonic pancreas development [26]. Epithelial branching leads to the morphogenesis of different domains, which become most apparent at the beginning of the secondary transition. There is mounting

Figure 4.2 Cytodifferentiation in the developing pancreas. The tip domain houses MPCs, which give rise to pre-acinar cells, and bipotent duct/endocrine cells (gray) that subsequently reside in the trunk of the branching epithelium and give rise to duct cells (white) or hormone-producing endocrine progenitor cells (colored cells). In the mouse, endocrine progenitor cells express Neurog3 and were determined to be unipotent, such that each Neurog3+ endocrine progenitor is destined to become a particular hormone-expressing endocrine cell type, including insulin-expressing β cells, glucagon-expressing α cells, somatostatin-expressing δ cells, ghrelin-expressing ε cells, and pancreatic polypeptide-expressing PP cells. Some of the transcription factors responsible for the development of each specific islet cell type are outlined.

evidence that MPCs exist within these emerging epithelial domains. In particular, Melton and colleagues proposed the identity of the MPCs as those cells expressing the factors Ptf1a, Pdx1, c-Myc, and Cpa1 [31]. This concept stemmed from a genome-wide transcription factor analysis in mouse pancreas tissue at embryonic day (E) 14.5, whereby gene expression patterns were identified to segregate into particular domains of the developing pancreas. Specifically, patterns emerged

Table 4.2 Key transcription factors in β-cell development

	Alternate names	Mouse knockout pancreas/β-cell phenotypes	Human digestive disease relevance
Hhex	Hex, Prh, Prhx	loss of foregut endoderm, specification of ventral pancreas	none associated
Foxa2	Hnf3β	loss of foregut endoderm, insulin hypersecretion	type 2 diabetes susceptibility
Sox17	–	depletion of definitive endoderm	none associated
HNF1β	Tcf2, Hnf2	required for visceral endoderm and gut morphogenesis	MODY5
Pdx1/Ipf	Ipf, xlHbox8	pancreatic hypoplasia, β-cell secretory dysfunction	MODY4/type 2 diabetes susceptibility, pancreatic hypoplasia
Ptf1a	p48	pancreatic hypoplasia and transdetermination of pancreas to duodenum	pancreatic hypoplasia
Mnx1	Hb9, Hlxb9	dorsal bud agenesis, reduced β-cell mass	neonatal diabetes
Sox9	–	pancreatic hypoplasia, early differentiation	none associated
Neurog3	Ngn3, Atoh5	lack of all endocrine cell types	congenital malabsorptive diarrhea with variable onset diabetes
Neurod1	Beta2	diminished endocrine cell mass and diabetes	MODY6
Isl1	–	dorsal bud agenesis, lack of islets	neonatal diabetes
Pax6	–	reduction of β cells	none associated
Arx	–	loss of α cells and increase of β cells	none associated
Pax4	–	loss of β cells and gain of α cells	MODY9
Nkx2.2	–	arrested β-cell differentiation	none associated
Nkx6.1	–	loss of β cells in the secondary transition	none associated
Mafa	V-MafA	normal differentiation of β cells, impaired function	none associated
Mafb	V-Mafb	embryonic lethal; reduced numbers of β and α cells	none associated

that could be grouped into five domains: pan-epithelium, tip, trunk, mesenchyme, and vasculature. Genes discovered to be expressed in the tip domain later segregated into differentiated acinar cells, whereas genes expressed in the trunk domain were identified in the ducts or differentiated endocrine cells. Taken together, data from multiple studies suggest that MPCs residing in the tip domain will give rise to pre-acinar cells, destined to become exocrine tissue, and bipotent duct/endocrine cells that reside in the trunk of the branching epithelium (Figure 4.2).

Endocrine versus exocrine cell fate decision

It is in the early developing pancreatic domain, when progenitor cells are multipotent, that the endocrine versus exocrine decision is made. In the mouse, Ptf1a is located in the early pancreatic progenitor cells and over time becomes restricted to expression in the branching tips and then differentiated acinar cells [32]. At the beginning of pancreas development the transcription factors Nkx6.1 and Nkx6.2 are co-expressed in the MPCs before becoming restricted and separated in their expression pattern. The Nkx6 factors and Ptf1a have been noted to function antagonistically in the decision between endocrine and exocrine cell fates, such that Nkx6 factors promote the endocrine decision whereas Ptf1a promotes the exocrine decision [33].

The endocrine versus exocrine cell fate decision is also influenced by the level of expression of the transcription factor Neurogenin3 (Neurog3) in the progenitor cells. Specifically, a high level of Neurog3 is required for commitment to the endocrine fate [34]. Moreover, Notch signaling is used in the trunk domain to subdivide this compartment between endocrine and ductal cells via a lateral inhibition mechanism. Neurog3 upregulates expression of the Notch ligand Delta-like 1 (Dll1) in endocrine progenitors, which activates the Notch pathway in neighboring cells thereby repressing their differentiation into endocrine cells.

The endocrine progenitor cell

The culmination of many studies has confirmed that in the developing mouse pancreas, the transcription factor that defines the endocrine progenitors is Neurog3. *Neurog3*-null mice exhibit absence of endocrine cells in the pancreas, and such mice develop neonatal diabetes and die shortly after birth [35]. During mouse pancreas development a subset of hormone-expressing cells is observed as early as E9.5, whereas the major wave of endocrine differentiation occurs during the secondary transition. Lineage tracing experiments using genetically-engineered mouse reporter lines identified that, regardless of when the endocrine cell differentiates, all hormone-expressing cells are derived from cells that previously expressed Neurog3 [36,37].

The process of endocrine differentiation has also been linked to the morphological process of delamination of the progenitor cells from the pancreatic epithelium. Interestingly, the delamination of progenitor cells is initiated in the cells that express

Neurog3 [38]. Moreover, the subsequent differentiation into different endocrine cells types is influenced by the timing of Neurog3 expression. Specifically, altering the temporal expression of the gene encoding Neurog3 in the mouse influences the competence of progenitor cells to differentiate into the specific endocrine cell types, such that earlier expression produces almost exclusively α cells, whereas later expression produces varied ratios of all hormone-expressing cell types [39].

Previous models of pancreas development suggested that each Neurog3-expressing cell could give rise to any subsequent differentiated endocrine cell type. However, this perspective has been challenged by lineage tracing experiments using genetically-altered mice, which demonstrated that each Neurog3-expressing endocrine progenitor cell is in fact unipotent, and therefore destined to become a particular single-hormone expressing endocrine cell type [40] (Figure 4.2). The implication of this discovery is that the transcription factor "code" responsible for the differentiation of each hormone-expressing cell type may be delineated before endocrine progenitors are specified.

Clearly, the expression of Neurog3 is of great significance to the development and differentiation of endocrine cells in the mouse. However, the effect of loss of this transcription factor in other species is not identical to the mouse. For example, in zebrafish Neurog3 is not observed in the pancreas [41]. Homozygous mutations in Neurog3 have been identified in humans, resulting in congenital malabsorptive diarrhea and childhood-onset diabetes [42,43], but without congenital loss of pancreatic endocrine cells (as seen in the mouse). Nevertheless, the absence of enteroendocrine cells was noted in these individuals.

Other transcription factors are also expressed in the early endocrine cell population, and genetic deletion studies identified these factors to be crucial to endocrine cell differentiation. In particular, the transcription factor Islet1 (Isl1) is expressed in all mature, non-replicating islet cell types. Interestingly, Isl1 expression is also observed in the mesenchyme that surrounds the early dorsal pancreatic bud. The dorsal pancreatic mesenchyme does not form in *Isl1*-deficient mouse embryos, leading to a loss of exocrine differentiation in the dorsal pancreas; the pancreas is also devoid of all islets in these mice. Loss of the transcription factor Pax6 in the mouse leads to death shortly after birth. The pancreas of Pax6-deficient animals is devoid of α cells and has marked reductions in β, δ, and PP cells [44]. Whereas a human mutation in the *ISL1* gene has been identified in a patient with type 2 diabetes [45], no link to diabetes has been observed in humans with mutations in the *PAX6* gene. Therefore similar to Neurog3, the functional importance between lower organisms and humans may not be completely conserved for genes involved in endocrine differentiation.

What makes a β cell?

The insulin-producing β cell is perhaps the most intensely studied endocrine cell type, largely because of the implications for understanding the pathogenesis and treatment of diabetes. Many mouse models have clarified the factors necessary for β-cell differentiation, development, and maturation (see Table 4.2). One such factor is the basic helix-loop-helix transcription factor Neurod1. Interestingly, Neurod1 is expressed in all endocrine cell types except the somatostatin-producing δ cell, and targeted disruption of the *Neurod1* gene in mice results in severe reduction in α and β cells, and in neonatal diabetes owing to β-cell apoptosis [46]. The Maf family of transcription factors is also involved in the pathway of α- and β-cell differentiation. Both MafA- and MafB-deficient mouse models have pancreatic phenotypes. Loss of MafB leads to perinatal lethality and, although the total endocrine cell mass is unaffected, the pancreas shows reduced numbers of α and β cells [47]. By contrast, mice with a targeted deletion of gene encoding MafA are born viable and with normal islet cell numbers, but demonstrate β-cell dysfunction with advancing age, leading to glucose intolerance and diabetes [48]. In these mice, β-cell genes, including those encoding insulin, Neurod1, and Glut2, are significantly reduced. Owing to its importance in β-cell function, MafA is considered as a marker for mature, functional β cells.

Interestingly, a number of factors expressed broadly in early pancreas development become restricted to specific endocrine cell types during the secondary transition and acquire additional function in the differentiation or maturation of these cell types. One particular example is Pdx1. Whereas mice with a homozygous deletion of the gene encoding Pdx1 are born without a pancreas, haploinsufficiency of *Pdx1* results in glucose intolerance [49,50]. Virtually identical phenotypes are observed in humans with respective homozygous and heterozygous mutations in *Pdx1* [44]. After the pancreas is fully developed, Pdx1 is expressed primarily in β cells and is necessary for β-cell function, including transcriptional activation of several β-cell genes [51]. Nkx2.2 is another transcription factor that shows expression in the early pancreatic progenitors but becomes restricted to specific endocrine cell populations later in development [52]. Loss of Nkx2.2 in the mouse results in the complete absence of differentiated insulin-producing β cells, a significant decrease in α and PP cells, and a concomitant increase in ghrelin-expressing ε cells [53].

Mouse models have also identified specific factors necessary for the differentiation of the glucagon-expressing α cell. In particular, deletion of the transcription factor *Arx* results in hypoglycemia and neonatal lethality. Given that Arx is expressed in all endocrine cells except the β cell, the pancreas of the *Arx*-null mouse has altered endocrine cell ratios: a complete absence of α cells and an increase of β and δ cells. Conversely, the misexpression of the *Arx* gene in either Pdx1- or Pax6-expressing cells results in a loss of β and δ cells and an increase in α and PP cells [48]. Moreover, compound mutants have demonstrated the complexity of transcription factor interactions and the importance of Arx function to endocrine cell development. Specifically, deletion of the *Arx* and *Pax4* genes result in the loss of α and β cells but an increase in δ cells [48], and the *Arx/Nkx2.2*

compound mutant pancreas showed a restoration of the PP cell population that was lost in the *Nkx2.2* null pancreas [52].

The evidence for the relevance of transcription factors to human pancreas development and disease is highlighted by the discovery that mutations in a number of transcription factors identified to be important in pancreas development in the mouse also display pancreas-related phenotypes in the human. Mutations or deletions of many of these factors have been established as the cause of monogenic forms of diabetes known as maturity-onset diabetes of the young (MODY) [54], or as the cause of human syndromes that include diabetes [42,43,55–58] (Table 4.2).

Translating pancreas development into cell-based therapies for diabetes

The knowledge gained from decades of pancreas development research has stimulated the translational pursuit of engineering insulin-producing β cells *in vitro* for therapeutic purposes. Specific extrinsic factors, including FGF, RA, and inhibitors of BMP or Shh signaling, have been applied to mouse and human embryonic stem cells in culture to successfully drive these malleable cells toward a pancreas fate [54] (see Figure 4.3). More recently, success in the creation of pluripotent, embryonic-like stem cells from somatic cells has opened the possibility of generating patient-specific β cells as cell replacement therapies for diabetes [55]. To date, however, such techniques have resulted in compound or mixed populations of hormone-producing cells, which have little or no capacity for glucose-stimulated insulin secretion when generated wholly *in vitro*, suggesting that many intrinsic and/or extrinsic factors involved in the cytodifferentiation of pancreatic progenitors remain to be identified. In the mouse, the genetic manipulation of certain intrinsic factors, that is, Pdx1, Neurog3, MafA [59], or the induction of severe pancreatic injury [60], has also identified the capacity of differentiated cells in the pancreas to be "reprogrammed" to β cells. Therefore the continued merging of developmental

biology research with *in vitro* differentiation technology may produce the long awaited therapeutic cure for diabetes.

Postnatal β-cell growth and maintenance

Following the secondary transition, the total mass of the pancreas increases substantially, but β cells comprise only about 1–2% of this cellular mass in the mature adult pancreas. Despite this relatively small percentage, the states of β-cell mass and function represent perhaps the greatest determinants in overall glucose and lipid homeostasis in virtually all types of metabolic disorders [61]. Two fundamental concepts regarding postnatal β cells have emerged over the past two decades: (1) although β cells were considered to be a postmitotic cell type in an adult mammal, it is now understood that they indeed exhibit a slow rate of turnover that decreases with age [62], and (2) the mass and function of β cells (and therefore the balance between new cell formation and death) can be dynamically altered to an extent to compensate for the physiologic or pathologic state of the organism [60]. A major focus and area of controversy has been the mechanisms that underlie postnatal β-cell growth and maintenance. From the discussion in the preceding sections on prenatal development, it is evident that formation of most β cells during embryogenesis occurs through a process known as neogenesis, in which new cells arise from the differentiation of stem or progenitor cells. Although some studies suggest the existence of multipotent stem cells within the postnatal rodent pancreatic epithelium, such cells normally do not give rise to significant numbers of new β cells in adult animals.

Neonatal β-cell turnover

The neonatal period between birth and weaning in rodents is characterized by a high rate of β-cell turnover and net increase in β-cell mass. Turnover is defined as the dynamic formation and loss of cellular mass [62]. Because there is no

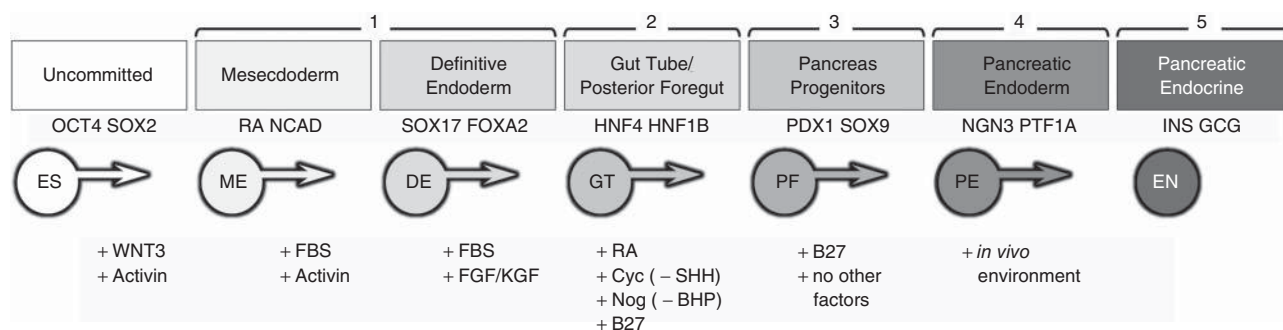

Figure 4.3 *In vitro* differentiation of pancreatic β cells. A schematic representation of a five-step embryonic stem (ES) cell differentiation protocol that mimics *in vivo* events of pancreatic organogenesis and differentiation through addition of secreted signaling factors. Important tissue markers that are shared with development of embryonic tissues are listed below each stage. (1) ES are guided through the mesendoderm (ME) stage to definitive endoderm (DE), then (2) to primitive foregut tube (GT), (3) posterior foregut (PF), and (4) pancreatic endoderm (PE). (5) The factors regulating the final stage of differentiation into endocrine cells (EN), cannot be performed effectively *in vitro*, and cells are transplanted into a murine host to complete cytodifferentiation by receiving physiologic cues. Additional abbreviations: FBS, fetal bovine serum; Cyc, cyclopamine (SHH antagonist); Nog, Noggin (BMP antagonist); B27, defined tissue culture supplement. longitudinal, noninvasive way to measure β-cell turnover in a given animal, the techniques that estimate β-cell turnover are based on cross-sectional studies from cohorts of animals that analyze steady-state β-cell mass, new β-cell formation (primarily by replication), and β-cell death. Nonetheless, studies using thymidine analog (BrdU) incorporation estimate that in the neonatal rat the rate of β-cell replication is as high as ∼20% new cells per day at 2 days of age, and falling to about ∼10% new cells per day by the time of weaning [63]. By contrast, replication rates in adult rats and mice are much lower, in the range of 0–2% new cells per day [63,64]. Although replication is thought to be the primary source of new β-cell formation during this period, studies of thymidine analog incorporation cannot detect specific contributions from neogenesis, which is thought to play a role during the neonatal period [65]. Balancing this rate of replication is, in part, the rate of apoptosis that appears to be elevated during the neonatal period, with the frequency of apoptotic cells rising as high as ∼4% (compared to less than 0.4% in adult rats) [63]. However, it should be noted that the true rate of β-cell death is very difficult to measure because dead/dying cells may be cleared more rapidly than can be measured by tissue morphometry, and other forms of death (necrosis) are not typically measured.

The foregoing studies in rodents appear to also reflect the dynamics of β-cell turnover in humans. Based on autopsy studies, the replication rate of β cells appears highest in children, especially infants (coincident with increases in β-cell mass during early life), then declines in adulthood [66]. Taken together, these studies suggest a dynamic remodeling of β cells and their mass in the neonatal/early postnatal period, and mechanisms underlying the increase in β-cell replication rate have been the focus of intense investigation [65]. The growth factors insulin and insulin-like growth factors (IGFs) are obvious candidates, given the autonomous production of both by β cells in the early postnatal period. Elimination of IRS-2 (a key protein in growth factor signaling) results in the failure to maintain β-cell mass in the face of increasing insulin resistance as mice age, suggesting a potential β-cell growth-promoting effect of this signaling cascade [67]. However, elimination of either of the two genes encoding mouse insulin, the insulin receptor in β cells, or the IGF-1 receptor in β cells in mice does not affect neonatal replication or accrual of β-cell mass [68]. Curiously, key cell cycle activators (Cyclins D1 and D2 and Cdk4) also appear dispensable for neonatal β-cell replication, but not for maintenance of β-cell mass in adulthood [69]. These results collectively suggest that the early signals driving replication of β cells during embryogenesis differs from signals that drive accrual of β-cell mass in early life (see later). The physiologic significance of the high neonatal β-cell turnover is a matter largely of speculation. Considering that neonatal islets show diminished or absent responsiveness to glucose-stimulated insulin secretion suggests that the neonatal turnover may be important for the eventual refinement and maturation of β cells [62]. Intriguingly, it has been suggested that this early

turnover of β cells may result in exposure of β-cell autoantigens and trigger the pathogenesis of type 1 diabetes in susceptible individuals [70], although more recently this hypothesis has been challenged in mouse models [71].

β-Cell growth with aging

For many years it was speculated that β cells, much like neurons, were postmitotic and that their turnover in the mammal was minimal or zero. Over the last two decades, studies in mice have suggested a more dynamic picture, wherein β-cell mass can change in response to physiologic states such as growth, pregnancy, and obesity [72]. Following weaning in rodents, there is considerable increase in β-cell mass that reflects the increase in body mass and an adaptation to the needs for increased insulin release. β-Cell mass is reflective of the changes in β-cell formation, individual β-cell size, and β-cell death. Whereas replication can be fairly reliably estimated using thymidine analog incorporation strategies, the rate of death is much more difficult to measure, primarily because dying β cells are cleared from the islet rapidly and therefore are difficult to detect. Thus, in studies of mature rodents, the turnover of β cells is estimated in large part from rates of replication. Studies in rats have shown that β-cell mass increases in a near-linear fashion with body weight [63,73]. The replication rate of β cells declines with age (to ≤2% per day in 20 month-old animals), but does not approach zero, and β-cell volume increases with age. These results suggest a low, but clearly measurable, turnover of β cells in adult rats and a β-cell lifespan in the order of 1–3 months. Using a continuous BrdU labeling strategy in mice, a much lower rate of replication has been estimated in adult mice, leading to the conclusion that β-cell turnover is near zero [72]. Human β-cell mass accrual and replication rates are significantly more difficult to estimate, largely because cross-sectional data from a genetically diverse population must be extrapolated using static markers of replication (e.g. Ki67 or BrdU). Nevertheless, data from human autopsy samples suggest that there is accrual of β-cell mass with increasing body mass in children, with progressively decreasing potential for replication with age [66,74].

Compensatory β-cell growth: adaptation to demand

The concurrent growth of β-cell mass with growth of the organism is but one example of the capacity of β cells to adapt to the increasing metabolic demands of peripheral tissue. Physiologic states of tissue resistance to insulin action, such as obesity and pregnancy, pose similar challenges to the β cell. It was recognized as early as the 1930s from autopsy studies that the average size of the islets of Langerhans increases as humans become overweight [75]. Similar findings are seen in a variety of mouse, rat, pig, and other animal models of obesity, where both β-cell size and number are reportedly increased. The increase in β-cell mass in response to obesity reflects an adaptation to the increased insulin demands imposed by the resistance to insulin action in liver, muscle, and fat. Pregnancy

imposes a challenge on the β cell similar to obesity, as pregnancy causes a state of tissue resistance to insulin. In either obesity or pregnancy, inherent defects that prevent increases in β-cell mass and insulin release may be the underlying causes for the development of diabetes. For example, in mouse models haploinsufficient for the gene encoding Pdx1, there is impaired compensation for insulin resistance in terms of both β-cell mass and function, with ensuing glucose intolerance and diabetes [76]. Similarly, humans with heterozygous mutations of *Pdx1* (a disorder known as maturity-onset diabetes of the young 4, or MODY4) develop diabetes with age, typically in adolescence or early adulthood [54]. In these individuals, it is thought that β-cell compensation for linear growth and/or age-related insulin resistance is impaired. Pdx1 is crucial not only in the regulation of genes encoding β-cell proteins that are important in insulin secretion, such as the glucose transporter Glut2, glucokinase, and insulin, but also in the regulation of genes that are downstream of the growth-promoting insulin receptor/insulin-like growth factor 1 (IGF-1) receptor signaling cascade [51].

Origins of new β cells in the adult: neogenesis, transdifferentiation, and replication

Considering the relatively small mass of β cells with respect to overall body mass, there has been a vigorous attempt over the last decade to define better the potential sources of new β cells in the growing mammal and to harness such sources for the creation of new β cells for those who are deficient. As discussed in the foregoing section, new β-cell formation was largely estimated by rates of β-cell replication, but excluded potential contribution from neogenesis. Therefore, if neogenesis were a major contributor to new β-cell formation, then rates of β-cell turnover were substantially underestimated. Speculation that a precursor β cell, or a true MPC, exists in the pancreas arose from early observations in rat models that new insulin-positive cells emanated from cells within proliferating [77]. The question of the origin of new β cells in models of pancreas regeneration has been addressed using lineage tracing analysis in mice to show that β cells arise almost exclusively by replication of preexisting insulin-positive cells rather than via neogenesis [78], a finding confirmed in subsequent studies in mice [79]. However, these findings do not exclude the possibility that a rare, insulin-positive cell type with high proliferative capacity (i.e., a cell type that would not be defined as a mature β cell) has the ability to serve as a MPC, or that under certain conditions other cell types within the pancreas (i.e., facultative stem cells) have the capacity to differentiate to β cells. Thus, investigators continue to posit the existence of these alternative cell types in the pancreas whose differentiation into mature β cells may recapitulate a pathway of transcription factor expression similar to that seen in development [80].

Because all pancreatic epithelial cell types arise from a common Pdx1-positive precursor, it has been proposed that mature pancreatic cells of either exocrine or endocrine origin may have the capacity to directly differentiate into β cells without the need for de-differentiation into a precursor form (a process known as "transdifferentiation"). In this respect, although lineage tracing analyses have all but ruled out the possibility that mature acinar cells transdifferentiate under normal conditions to β cells in mice [81], the ectopic expression of the key developmental transcription factors Pdx1, Neurog3, and MafA in acinar cells enables a program that allows their conversion to insulin-expressing cells [59]. Similarly, under specific experimental conditions in mice, mature α cells have the capacity to transdifferentiate into β cells [48]. Taken together, these studies reinforce the theme that different mature cell types of the pancreas that arise from a common origin have the capacity to exhibit phenotypic characteristics of one another, and leave open the possibility that under specific conditions such cell types may transdifferentiate to offset loss of β-cell mass.

Whether any of the mechanisms discussed earlier— neogenesis or transdifferentiation—play a role in human β-cell replenishment remains uncertain. Interestingly, studies *in vitro* suggest the potential existence of precursor cell types in the human pancreas [80], but it is unknown whether and to what extent such cells give rise to β cells normally in humans. To date, the best available data indicate that replication of preexisting β cells is the likely mechanism for accrual of β-cell mass during human growth [66,74,82].

Regulators of β-cell growth: growth factors and cell cycle regulators

A host of circulating factors appears crucial in the stimulation of early postnatal β-cell growth. As the growth of β cells closely parallels the growth of the organism during this early phase, it is relevant to note that nutrients, particularly glucose, remain among the most important factors contributing to β-cell replication during this period. Thus, intravenous glucose infusions for even short time periods (96 hours), which only mildly increase serum glucose concentrations, result in fivefold increases in β-cell replication in young mice [83]. Although an effect of glucose to directly stimulate β-cell replication has been proposed, it is possible that its effect may be caused by its stimulation of insulin release from β cells, such that insulin in an autocrine manner serves as the mitogen. Insulin and insulin-like growth factor 1 are classic growth factors that signal through related transmembrane receptors with associated receptor tyrosine kinases. Mice lacking the insulin receptor in β cells display impaired insulin release associated with reduced β-cell mass, whereas mice lacking the IGF-1 receptor in β cells display impaired insulin release without associated loss of β-cell mass. Interestingly, loss of both the insulin receptor and IGF-1 receptor in β cells results in severe reductions in β-cell mass and frank diabetes [68]. These data suggest that the insulin and IGF-1 signaling pathways function in distinct, but complementary ways, notwithstanding that both receptors share similar downstream signaling molecules (insulin receptor substrate proteins, phosphatidyl inositol-3 kinase, and protein

kinase B). In recent years, a host of other growth factors has also been shown to positively influence β-cell replication and/or function (see Table 4.3), and include factors released not only from the islet, but also from a variety of organs, such as bone (osteocalcin), the anterior pituitary (growth hormone, prolactin), gut (glucagon-like peptide 1), fat (leptin, adiponectin), and brain (serotonin). Whereas these metabolites and growth factors can directly or indirectly impact β-cell replication, it should be noted that their effects are much greater in younger mice and humans and much less so as aging occurs.

Although the effects of the aforementioned growth factors result in enhanced β-cell replication and insulin release, the pathways leading to activation of cellular replication machinery differ depending upon the factor [68]. Nevertheless, all factors ultimately impinge upon the components of the cell cycle. Transit through the cell cycle requires the β cell to exit the resting state (G0) and traverse G1, S, G2, and M states [82]. For the most part, replication of β cells is largely driven by factors that control the G1/S transition of the cell cycle. Genetic manipulation studies in mice have emphasized the importance of not only activators of the G1/S transition, but also inhibitors, such that the balance between the two appears to regulate the overall drive for β-cell replication. Cyclins and cyclin-dependent kinases (Cdks proteins) are major activators of β-cell replication. Cyclins and Cdks negatively regulate the major pocket protein known as pRb, which functions as a

"molecular brake" on the G1/S transition. Cyclins and Cdks appear crucial in the accrual of early postnatal β-cell mass, but interestingly not in the generation of β-cell mass in the embryo. Mice homozygous null for the gene encoding CyclinD2 or Cdk4 exhibit no alterations in β-cell mass at birth, but show loss of mass accrual with age [84,85]. Similarly, loss of the gene encoding CyclinD1 does not affect embryogenesis, but heterozygosity of the *CyclinD1* gene in combination with homozygous loss of *CyclinD2* results in even further loss of β-cell mass with age and severe, life-threatening diabetes [84]. The cyclin-dependent kinase inhibitors (CKIs) — including p15^{Ink4b}, p16^{Ink4a}, p18^{Ink4c}, p19^{Ink4d}, p21^{Cip}, p27^{Kip1}, and p57^{Kip2} — are major negative regulators of β-cell proliferation, and their actions appear to predominate in later life, where these factors may be responsible for inhibition of β-cell proliferation in aging mammals [82].

Recent studies have clarified the human islet G1/S cell cycle protein expression pattern [86]. Whereas murine and human islets differ in their expression of the G1/S cell cycle activator Cdk4 (humans express Cdk6), they have virtually all G1/S CKIs in common. This latter observation may be crucial in the understanding of why β-cell replication is so dramatically reduced in aging humans. A particularly intriguing target in this respect is p16^{Ink4a}, whose expression in β cells is up-regulated as mice age, and may serve as a target to prevent the age-induced limitations in β-cell mass [87]. The potential for β cells to undergo uncontrolled replication as a result of deregulation of G1/S cell cycle proteins is dramatically emphasized by mutations in the gene encoding Menin in both mice and humans. Menin is a tumor suppressor transcription factor that negatively regulates the expression of p18^{Ink4c} and p27^{Kip1}, and its absence or mutation results in the tumorigenic transformation of a variety of endocrine tissues (including β cells) in a syndrome known as multiple endocrine neoplasia 1 (MEN1) [88].

Conclusions and areas of future study

In the early twentieth century, the discovery of insulin dramatically transformed the treatment of diabetes mellitus. Indeed, it was thought that the administration of insulin might reduce stress and allow for the time necessary to regrow new β cells, a consequence that was never observed. In the ensuing decades, the incidence of type 2 diabetes rose to dramatic proportions, and as a result the quest for β-cell-based therapies for diabetes has seen broader appeal. As discussed, more recent research has led to dramatic insights into pancreas and β-cell development, and into the postnatal life cycle of the β cell. Although most of these insights derive from studies in lower animal species, their applicability to the treatment of human diabetes mellitus has risen to the forefront of discussion in recent years. Importantly, we know now that although β cells have the capacity to expand in the postnatal period, in humans the window for such expansion may be limited to the first 2–3 decades of life, and thereafter the ability to compensate for

physiologic stressors (such as obesity) diminishes with age. As such, strategies for therapies for diabetes in the future may well focus on ways to enhance β-cell replication or to engineer new β cells. With respect to the latter, studies of embryonic development have enabled important strides in generating β-like cells from primitive biologic precursors (e.g. human embryonic stem and induced pluripotent cells). Yet, these engineered cells do not exhibit the full phenotypic spectrum of true β cells, such as the ability to release insulin in response to a physiologic glucose challenge. The knowledge that all cells of the pancreas arise from a common progenitor has raised awareness that plasticity of fully differentiated pancreatic cell types may be much greater than originally thought. In this respect, studies of transdifferentiation of other abundant pancreatic cell types (such as α cells or acinar cells) to β cells *in vivo* may hold promise for the treatment of human diabetes, but to date no clear examples of human cell transdifferentiation have emerged. As the burden of diabetes increases, the need to translate research from lower animals to humans increases, and in the coming years it is likely that the generation of better model systems that mimic the human condition will become a greater priority.

CHAPTER 5

Pancreatic morphology in normal and diabetic states

Rebecca L. Hull and Steven E. Kahn

Division of Metabolism, Endocrinology and Nutrition, Department of Medicine, VA Puget Sound Health Care System and University of Washington, Seattle, WA, USA

Key points

- The pancreas comprises exocrine and endocrine compartments, which produce and release digestive enzymes and glucoregulatory hormones, respectively.

- The pancreatic islet is predominantly composed of endocrine (β, α, δ, F, and ε) cells, but is also supplied by an extensive capillary network and receives both parasympathetic and sympathetic innervation.

- The morphologic arrangement of these numerous cell types within the islet, and intercellular communication between them appears to be critical for normal endocrine function.

- The islet extracellular matrix is an emerging site of regulation of β-cell function and survival, and is disrupted or degraded in diabetes.

- In type 1 diabetes, an almost complete obliteration of β cells occurs, predominantly via T-cell-mediated autoimmune destruction.

- In type 2 diabetes, pancreas weight is relatively normal, but loss of β cells also occurs, albeit to a lesser extent than in type 1 diabetes.

- β-Cell loss also occurs in cystic fibrosis-related diabetes, suggesting that exocrine pancreatic abnormalities can have profound effects on the islet.

- In type 2 diabetes, the etiology of β-cell demise is complex. Nutrient excess, amyloid deposition and inflammation have all been proposed as underlying mechanisms of β-cell loss.

Pancreatic anatomy and morphology

The pancreas is located in the upper abdominal cavity, in close proximity to both the duodenum and spleen (Figure 5.1(a)). In humans, pancreatic weight ranges from 40–150 g [1,2]. Embryonically, the pancreas develops from two separate buds of the primitive foregut, yielding duodenal (ventral) and splenic (dorsal) lobes [3]. Once developed, these constitute the head and body/tail, respectively. These regions of the pancreas are similar, aside from some differences in the distribution and composition of pancreatic islets (discussed later).

Functionally, the pancreas comprises two independent compartments, the exocrine and endocrine pancreas, which derive from common endodermal precursor cells during development [3]. The exocrine pancreas accounts for the vast majority of pancreatic mass and consists of lobules, each comprising acini that connect into a network of ducts (Figure 5.1(b)). Acinar cells demonstrate a characteristic morphology at the electron microscopy level including electron-dense zymogen granules and an extensive endoplasmic reticulum (ER) network. This ultrastructural organization is consistent with the chief function of the exocrine pancreas, namely to secrete digestive enzymes including amylase and trypsin via the pancreatic ductal system into the gut. The endocrine pancreas comprises islets of Langerhans, roughly spherical structures that contain hormone-producing cells. Islets constitute only a small minority of pancreatic mass but are critically important for metabolism throughout the body, and especially for maintenance of glucose homeostasis. This was first shown in 1890 by studies in which pancreatectomy in dogs resulted in diabetes [4]. In the human pancreas, it has been estimated that there are one to two million islets scattered throughout the exocrine pancreas, which together comprise approximately 2% of pancreatic mass [5,6]. While the function of these two pancreatic compartments differ significantly, they exist in close proximity to one another, and evidence exists for interactions between them. Specifically, islets are distributed throughout the exocrine pancreas. Islet hormone-rich blood perfuses the exocrine pancreas [7], and the islet hormones, insulin and pancreatic polypeptide, have been shown to stimulate amylase secretion from the exocrine pancreas, while glucagon inhibits amylase secretion [8–10]. This suggests that the functional status and viability of the islet can influence function/viability of the exocrine pancreas and potentially vice versa.

Islet composition and morphology

Despite the relatively small size of pancreatic islets, each comprising approximately 2000–4000 cells [11], every one is a complex mini-organ, containing numerous cell types (Figure 5.1(c)). Endocrine cells are, not surprisingly, the most abundant islet cell type and are characterized at the ultrastructural level by the presence of numerous secretory granules that contain endocrine hormones packaged and stored ready for immediate release in response to the appropriate stimulus. Additionally, endocrine cells contain a high density of mitochondria and abundant ER (although not so dense as the surrounding acinar cells). These endocrine cells are subcategorized based on their predominant hormone constituent, as follows.

Insulin-producing β cells are the predominant islet cell type. They were first identified in 1907 by silver staining [12] and were the second islet endocrine cell type to be described. β Cells comprise 50–80% of islet volume, depending on the species in question; rodent islets typically have a higher proportion of β cells (around 60–80%) [13,14], while nonhuman primate and human islets have a lower relative proportion (around 50–60%) [13–19] (Figure 5.2). The distribution of β cells within islets also differs among species. In rodents β cells are predominantly located in the core of the islet [13,14,19], while in nonhuman primate and human islets they are more evenly distributed throughout the islet (Figure 5.1(c)) [13,14,18]. Regardless of their location within the islet, for all species β-cell secretory granules have a characteristic appearance at the electron microscope level, with an electron-dense core that arises due to the formation of insulin hexamers which are cross-linked with zinc [11]. This granule core is surrounded by an electron-lucent

Figure 5.2 Islet endocrine cell composition in nondiabetic human subjects and those with type 1 and type 2 diabetes. Cell types are depicted as follows: β cells (blue bars), α cells (open bars), δ cells (diagonally striped bars), F cells (vertically striped bars) and ε cells (black bars). Source: Based on data from [2,13–18,23,26,59,68,70,79,95,97,98].

"halo" [11]. Release of insulin from β cells is critically important in regulating blood glucose levels, predominantly acting to suppress hepatic glucose production and to enhance glucose uptake in insulin-sensitive tissues such as skeletal muscle and adipose tissue. Mechanisms of insulin release are discussed in detail in Chapters 7, 8, and 9. In addition to insulin, β cells also produce islet amyloid polypeptide (IAPP), which is co-localized with insulin in secretory granules and is therefore co-secreted with insulin [20].

Glucagon-producing α cells were actually the first islet endocrine cell type to be described and are so called due to the alcohol fixation ("A"-cells) that was used to identify them [12].

These form the second most abundant endocrine cell type in the islet, but are far less abundant than β cells. In rodent islets, they account for around 15% of islet area [19], whereas in humans they are more abundant (around 35%; [13]) (Figure 5.2). Also, like β cells, α cells differ in their distribution within islets across species. In rodents, they are located almost exclusively in the mantle of the islet [13,14,19], while in human and nonhuman primate islets they are more evenly distributed throughout the islet (Figure 5.1(c)) [13,14,18]. Unlike β cells, whose abundance in islets is relatively constant throughout the pancreas, islets in the head of the pancreas are richer in α cells than those in the tail [19]. Glucagon-containing secretory granules differ in their appearance compared to insulin-containing granules, in that they lack an electron lucent halo. Thus, the entire secretory granule in the α cell is electron dense [21]. The hormonal effects of glucagon act to oppose those of insulin, stimulating hepatic glucose production, and being a critical mediator of the restoration of normal glucose levels following hypoglycemia. Glucagon secretion and its effects are described in Chapter 10.

Somatostatin-producing δ *cells* comprise the third islet endocrine cell type, being lower in abundance (<10% of islet cells) than either β or α cells (Figure 5.2). Their distribution within islets is similar to that of α cells, namely that in rodent islets δ cells occur predominantly in the mantle of the islet, while in primates and humans they are more evenly distributed throughout [13,14,18]. While few studies have systematically assessed δ-cell distribution in islets throughout the pancreas, δ-cell number does not appear to be markedly altered in islets from different regions of the pancreas [19]. Ultrastructurally, somatostatin-containing granules are homogeneous in appearance, similar to α-cell granules, but slightly less dense. The effects of islet-derived somatostatin are thought to be largely paracrine in nature due to its short half-life [22]. Somatostatin acts on receptors present on β and α cells, inhibiting both insulin and glucagon release.

Pancreatic polypeptide-producing F cells are less abundant still than δ cells, contributing on average less than 5% of islet cells. Again like α cells, their distribution differs throughout the pancreas, with islets in the head of the pancreas containing most of the pancreatic polypeptide-producing F cells [19,23]. Thus, islets in this region of the pancreas can contain up to 20% pancreatic polypeptide-containing cells, at the expense of α cells, which are decreased in this region. Conversely, in the rest of the pancreas, F cells only account for a 1–3% of islet cells [19,23] (Figure 5.2). F-cell granules are small, but similar in appearance to β-cell granules, containing an electron-dense core and electron-lucent halo. The release of pancreatic polypeptide from islets serves as an indicator of vagal outflow [24]. However, the function of pancreatic polypeptide, once released, is unclear. Some studies have suggested a role in inhibition of pancreatic enzyme and bile secretion, while others have suggested a role in modulation of food intake and energy expenditure [9,25].

Ghrelin-producing ε *cells* constitute the final known population of islet endocrine cells. These were first described during embryonic development [26], and were originally thought to reflect a population of multihormone positive cells. However, they have been shown to be present in adult islets, and are now considered a *bone fide* islet cell type [26]. Several studies have shown that ghrelin can suppress insulin release in humans and rodents [27,28]. However, whether this occurs due to a paracrine effect of islet-derived ghrelin or due to circulating ghrelin, which is largely produced in the stomach, is unclear at this time.

Islet vasculature. The islet is richly vascularized (Figure 5.3); while islets comprise only ∼2% of pancreas volume, they receive approximately 15% of the blood flow [29]. Arterioles enter the islet and branch into tortuous capillaries, which have been suggested to contact almost every endocrine cell in the islet. These then converge on collecting venules outside the islet [30]. Blood flow through the islet is thought to occur in two distinct patterns: first, arterioles penetrate the islet core and blood flow then emanates from the center of the islet outward. Second, blood flow can also proceed from one side of the islet to the other. These two patterns of blood flow appear to occur in islets from the same pancreas, with the former pattern being more frequent [31,32]. The concept that islet blood flows predominantly from the center to the mantle of the islet suggests that β cells are perfused

Figure 5.3 Scanning electron micrograph of a corrosion cast of a rat islet showing its extensive capillary network. Source: Adapted from Bonner-Weir 1982 [30]. Reproduced with permission of American Diabetes Association.

first [33]. Thus, α cells are exposed to high concentrations of insulin as they lie downstream of β cells in the islet vasculature, which tonically inhibit glucagon secretion. δ Cells are thought to be downstream of both β and α cells, consistent with the notion that somatostatin's effects to inhibit insulin and glucagon secretion occur in a paracrine, rather than endocrine manner. While the distribution of endocrine cells within nonhuman primate or human islets differs from that of rodents, it is likely that the same directional vascular supply exists [34,35].

Interestingly, there are differences in islet vascular density among species. Rodent islets contain a dense network of small capillaries [30,31], while human islets appear to contain fewer, larger capillaries (Hull, Brissova, Powers, unpublished observation) [36]. However, the functional consequence of this difference in capillary density is unknown. Islet capillaries are lined by a highly fenestrated endothelium, with islet endothelial cells containing around 10 times more fenestrae than capillaries in the neighboring exocrine pancreas [37]. This fenestration allows rapid exchange of nutrients and oxygen between blood and islet cells. However, in contrast to the liver which contains open fenestrae in its endothelium, islet endothelial fenestrae are gated; that is, covered by a glycocalyx, a semipermeable layer composed predominantly of the polysaccharide heparan sulfate [38]. This suggests some selectivity exists with respect to the molecules that can readily pass in and out of the islet capillary, although this is poorly understood. While the islet vasculature is critically important for providing adequate blood flow, supplying nutrients to islet cells and facilitating delivery of islet hormones to peripheral tissues, islet capillaries also provide important signals for normal islet endocrine growth and survival [39–41]. Finally, a vascular basement membrane, a specialized form of extracellular matrix, exists between islet capillaries and endocrine cells [36,37,40,42–44]. While this

extracellular matrix comprises predominantly collagen IV and laminins, it also contains a complex array of other proteins and proteoglycans including heparan sulfate proteoglycans, nidogens and hyaluronan which provide both structural support along with critical signals to both islet endothelial cells and endocrine cells, and participates in maintenance of normal function and proliferation of islet cells [40,45,46].

Islet innervation. The islet receives extensive autonomic input, via both sympathetic and parasympathetic branches of the autonomic nervous system [47]. These nerves do not form classical synapses with islet endocrine (or other) cells, but form terminals that release neurotransmitters in close proximity to islet cells which in turn act as important regulators of islet endocrine hormone release [47]. Islet innervation and its functional consequences are reviewed in detail in Chapter 9. Morphologically, islet innervation mirrors that of vascularization, with nerve fibers running parallel to islet capillaries [48]. Accordingly, rodent islets containing numerous, fine nerve fibers [48], while in contrast, human islets contain fewer, larger nerve fibers [49] (Figure 5.4).

Interactions among islet cell types. This highly ordered distribution of islet cell types has functional consequences. Islet cell types interact with one another by a number of different mechanisms including direct cell–cell contact, release of paracrine signals or via the extracellular matrix. For example, signaling via gap junctions is important for coordinating insulin release [50], while autocrine and paracrine signals such as GABA or somatostatin can enhance or suppress islet hormone release from neighboring endocrine cells [22,51,52]. Exposure of islets to neurotransmitters (reviewed in Chapter 9) or endothelial-derived factors such as hepatocyte growth factor, laminin or thrombospondin-1 can stimulate β-cell secretory

(a)   (b)

function and/or replication [41,45,53]. Conversely, β cells produce factors such as vascular endothelial growth factor, which are essential for islet endothelial cell viability and function [40,41]. Culture of β cells on extracellular matrix has profound effects to enhance islet cell proliferation, survival and function, suggesting another mechanism by which endocrine cells can be influenced by the islet vasculature [40,54]. Thus, changes in the abundance or organization of any one of the multiple islet cell types, or in exocrine pancreatic viability and function, likely has significant consequences for islet health and function and ultimately for glucose homeostasis.

Islet β cell regenerative potential

As discussed in Chapter 4, development and organization of islet endocrine cells occurs during embryogenesis and the early post natal period [3]. In rodents, continued β-cell expansion can occur into adulthood [55]. However, the ability of rodent β cells to replicate is severely limited with increasing age [56]. In humans, there is some plasticity in islet volume, particularly in very young individuals [57], but there is very limited regenerative potential of β cells in adults [57,58]. Physiologic stimuli such as insulin resistance, obesity, and pregnancy have been reported to result in increased β-cell mass in humans and rodents [59–62]; however, pancreatectomy, which is known to stimulate β-cell regeneration in young rodents [56,63], does not result in increased β-cell replication in older rodents [56] or adult humans [64]. Altering islet volume appears to be an exquisitely regulated process; in line with the requirement for maintenance of the organization of islet cell types, β-cell replication in rodents during pregnancy is preceded by islet angiogenesis (expansion of islet capillaries), suggesting that expansion of the islet vascular supply is required to allow expansion of the endocrine cell population [41]. Maintenance of the appropriate proportions and organization of islet endocrine cell populations in the face of islet expansion also occurs in response to high fat feeding in mice [65]. Islet innervation is also increased under conditions of high fat feeding and insulin resistance [66,67]. However, despite the ability of the islet cell population to expand in response to some physiologic stimuli, the limited capacity for β-cell expansion, especially with age, becomes a major problem in disease states where β cells are targeted for destruction.

Disturbances in pancreas/islet morphology in diabetes

Type 1 diabetes
Type 1 diabetes (T1DM) is classically associated with autoimmune destruction of β cells [68] (Figure 5.2). However, the pancreas is more broadly affected, with overall pancreas size being decreased in individuals with this form of diabetes [68,69],

and loss of exocrine tissue occurring close to areas of immune infiltration [70]. β-Cell destruction is largely a T-cell-mediated process, involving mainly CD8+ cells, but also including CD4+ cells and other immune cells such as macrophages and B cells [71,72]. Lymphocytic infiltration of islets is well documented in animal models [73,74]. However, the degree of infiltration can vary widely even among islets from the same animal in various stages of diabetes development [73,74]. Further, the extent of leukocyte infiltration in humans appears to be less than that seen in animal models, while the variability in affected islets is similar [70,72,75]. In human T1DM, insulitis is primarily reported in individuals with recent onset disease [70,76], although it has been detected in patients 8 years following diagnosis [72,76]. That insulitis occurs predominantly around the time of disease onset is consistent with the clinical observation that the largest decline in C-peptide responses occurs between 6 months prior to and 12 months following disease diagnosis [77,78]. Despite the variability in detectable insulitis, autoimmune destruction appears to result in eventual elimination of the majority of β cells [70,79]. However, β cells can persist for many years into the course of the disease [79,80] and low levels of β-cell replication have been documented in some [81], but not all studies [82]. Further, there is evidence for residual insulin release many years after the development of hyperglycemia [83]. This raises the possibility that β-cell destruction may not be complete and that regeneration may be possible. A recent study documenting the efficacy of stem cell therapy in rapidly reversing T1DM, in many cases up to 36 months of follow-up, provides support for this concept [84].

While β-cell destruction is widespread in T1DM, non-β-cell islet populations, particularly α cells, appear to be spared the autoimmune destruction [70]. However, despite the persistence of α cells in T1DM, their function is undoubtedly dysregulated. Specifically, meal-stimulated glucagon responses are exaggerated [85], while glucagon release in response to hypoglycemia is markedly impaired [86]. These abnormalities may be due to the lack of oscillating insulin levels, which would normally act to regulate glucagon release [87]. However, the lack of glucagon response to hypoglycemia is likely also impacted by the early loss of sympathetic nerve terminals in islets, which has been demonstrated in rodent models of T1DM [88,89] and in human T1DM [90]. This islet neuropathy is selective, with islet parasympathetic innervation appearing to be normal, at least in rodent models of T1DM [90].

Whether islet capillary density is altered in T1DM is currently unknown. Recently however, significant alterations in the extracellular matrix closely apposed to the islet vasculature have been described in human T1DM and animal models thereof [36,42]. Degradation of peri-islet extracellular matrix has been shown to correlate with leukocyte infiltration and β-cell loss in human T1DM and NOD diabetic mice [36,42]. Interestingly, however, once insulitis is resolved, peri-islet extracellular matrix is regenerated, even in the absence of insulin-positive cells, providing further support for a role of leukocytic infiltration in

the degradation of this extracellular matrix. Altered localization of the extracellular matrix component hyaluronan [91,92] and increased production of extracellular matrix degrading enzyme heparanase [93] have also been described in association with lymphocytic infiltration of islets in NOD diabetic mice, in common with other autoimmune diseases [94]. The contribution of these changes in extracellular matrix to diabetes onset and progression are not fully understood at present, but they may be important in allowing leukocytes to gain access to the islet, and are an active area of investigation.

Type 2 diabetes

Macroscopically, the pancreas appears largely unchanged in T2DM. Fibrosis in the exocrine pancreas has been described [95], suggesting some abnormality in the exocrine pancreas, but this has not been widely studied. In contrast, the presence of morphologic abnormalities in islets from subjects with T2DM has long been established. More than a century ago, Opie described decreased cell number and accumulation of what was later identified as islet amyloid [96]. Subsequently, it was confirmed that islet β-cell volume is decreased in T2DM [59,97], an observation has been reproduced in numerous studies, across several ethnic groups [15–17] (Figure 5.2). Butler et al. additionally showed that β-cell volume is also decreased in subjects with impaired fasting glucose, with the extent of reduction being intermediate between that of subjects with T2DM and nondiabetic controls [15]. Overall, the extent of β-cell loss reported varies widely among studies (0–63% reduction), most likely due to the variability of β-cell volume among subjects [16,17] and also to the site of sampling [16]. Similar to the situation in T1DM, islet α-cell mass has been shown to be maintained in T2DM, resulting in a relative increase in the α:β cell ratio [2,95,98]. In animal models, islet glucagon and pancreatic polypeptide immunoreactivity have been reported to be similar or increased relative to nondiabetic animals [99,100], while somatostatin immunoreactivity is more variable, being reportedly increased, similar or decreased in comparison to nondiabetic animals [99–101].

Alterations in density and/or morphology of islet capillaries have been described in a variety of rodent models of diabetes. Early in the course of hyperglycemia, distorted islet capillary morphology is present and with more advanced diabetes, loss of capillary density occurs and is frequently associated with islet fibrosis [102–108]. No published studies have been performed on human pancreas specimens, but our unpublished data suggest that while islet capillary morphology is distorted, islet capillary density is not decreased in T2DM relative to nondiabetic controls (Brissova, Powers, Hull, unpublished observation). Decreased islet innervation has also been reported in animal models of T2DM [109], but has not been determined in humans with the disease. Abnormalities in islet extracellular matrix have also been documented in human T2DM and animal models thereof. These include accumulation of islet amyloid,

which comprises the aggregated form of the β-cell peptide IAPP [17,95,110], and islet fibrosis occurring due to fibrillar collagen deposition [111,112].

Influence of exocrine pancreas abnormalities on islet morphology and function

Diseases affecting the exocrine pancreas are associated with diabetes. Acute pancreatitis has been associated with glucose intolerance and impaired insulin release, but this disturbance seems to be temporary [113], suggesting that exocrine pancreas abnormalities can impact islet function. In cases of chronic pancreatitis whose primary disease etiology is exocrine in nature, diabetes is present in the majority of cases [114]. However, pancreatitis is also more common in individuals with T2DM [95,115], making the link between exocrine disease and the subsequent onset of diabetes less clear.

Cystic fibrosis is an autosomal recessive disorder, arising due to one of several mutations in the cystic fibrosis transmembrane receptor (CFTR), a chloride channel, with disease onset usually occurring in childhood [116]. Lung disease is the primary manifestation of CFTR mutation. However, with improved treatment including lung transplantation, survival has significantly improved in recent years; as a result, other complications of cystic fibrosis are now more common. Pancreatic involvement, namely significant exocrine pancreas fibrosis is the second most common feature of cystic fibrosis, after lung pathology. Accordingly, cystic fibrosis-related diabetes complicates a large proportion of cystic fibrosis cases [117]. This form of diabetes does not seem to include underlying autoimmunity, suggesting its etiology differs from that of T1DM [118]. Unlike T2DM, insulin resistance does not appear to be a major underlying cause [119,120]. However, defective insulin release has been clearly demonstrated [119,120]. This is accompanied by decreased islet β-cell volume, which has been documented in several studies [121,122]. The mechanisms of β-cell loss in cystic fibrosis-related diabetes remain unclear, although islet amyloid deposition is also present in this population [123], suggesting that at least certain aspects of islet pathology share features with T2DM. Thus, some mechanisms that may explain β-cell loss in T2DM, and which are discussed later, are likely also pertinent to cystic fibrosis-related diabetes.

Mechanisms of β-cell loss in type 2 diabetes

While alterations in several islet cell types have been reported in T2DM or animal models thereof, only β cells have reproducibly been shown to be reduced [15–17,59,96,97]. Decreased β-cell volume in T2DM is associated with an increase in β-cell apoptosis [15,17], which occurs without a compensatory increase in β-cell replication due at least in part to the limited regenerative capacity of adult human islets [57,58]. Thus, mechanisms that result in β-cell apoptosis or other forms of β-cell death appear

to be critical for loss of β cells in T2DM. This process has been widely studied, and numerous mechanisms have been implicated.

Chronically elevated glucose and/or free fatty acids

Type 2 diabetes is characterized by increased circulating nutrients including glucose and free fatty acids (FFA). The literature clearly shows that chronic exposure of β cells to elevated glucose results in impaired β-cell function [124–126], but the data regarding cellular toxicity in response to this nutrient are more mixed. Exposure of cultured β-cell lines or islets to high glucose can, in some cases, result in increased β-cell death [127–132]. This may result from oxidative stress, activation of Fas receptor-mediated or mitochondrial apoptosis and may involve thioredoxin interacting protein (TXNIP) [127–129]. However, this effect of glucose to induce apoptosis is not a universal finding; several studies have demonstrated that the "toxic" effects of chronic hyperglycemia to impair β-cell function are reversible even after several weeks in culture [133,134]. Further *in vitro* and *in vivo* studies exposing β cell to elevated glucose have shown beneficial effects with glucose-promoting survival signals, suppressing apoptosis [135] or resulting in increased β-cell replication [136–138].

Exposure of islets/β cells to increased FFA levels alone, or in the presence of hyperglycemia results in impaired insulin release [139–141]. Culture of β cells in the presence of increased FFA, particularly palmitate, can also result in β-cell apoptosis [132,142–144]. This has been shown to occur via some of the same mechanisms as glucose-induced apoptosis, namely oxidative stress, ER stress and activation of the mitochondrial apoptosis pathway, and additionally may require increased ceramide or nitric oxide levels. However, similar to the observations with elevated glucose, high fat feeding or lipid infusions *in vivo* result in increased β-cell mass, as a result of increased β-cell replication [62,138].

Thus, taken together, the effects of nutrient excess appear to be more detrimental to β-cell secretory function rather than clearly inducing β-cell death, and some of these effects may be reversible.

Islet amyloid

As mentioned, amyloid deposition occurs in islets in the majority of subjects with T2DM, as well as in subjects with cystic fibrosis-related diabetes [17,95,110,123]. Accumulation of islet amyloid occurs due to the aggregation of the normally soluble β-cell peptide IAPP, which is then deposited in the islet extracellular matrix, between islet capillaries and β cells. This aggregation only appears to occur under conditions of diabetes or islet dysfunction, with islet amyloid being relatively rare in individuals without diabetes even in individuals with extremely high circulating levels of IAPP [110,145,146]. The underlying cause of this IAPP aggregation is unclear, but may involve impaired processing of IAPP from its precursor proIAPP [147–149] and/or interaction between IAPP and extracellular matrix components, principally heparan sulfate proteoglycans [150–153]. Human autopsy studies have yielded somewhat conflicting results, but the literature clearly demonstrates that the extent of islet amyloid deposition is associated with decreased β-cell volume [17,154] and increased β-cell apoptosis [17] (Figure 5.5). Studies using cultured human islets and transgenic animals expressing human IAPP (mouse and rat IAPP are not amyloidogenic) have further elucidated the mechanism(s) by which IAPP aggregation may elicit β-cell toxicity. Culture of human or transgenic mouse islets under conditions that favor amyloid formation, for example high glucose, result in amyloid-induced oxidative stress and increased β-cell apoptosis, thereby leading to a reduction in β-cell area [155–160]. This β-cell loss can occur via activation of the cell surface death receptor Fas [161], or cJun N-terminal kinase (JNK) and downstream activation of apoptosis [162]. Additionally, when human IAPP aggregation and thereby amyloid formation is

Figure 5.5 Relationship between islet amyloid deposition and decreased β-cell area (a) ($r = -0.76$, $p < 0.001$), and increased β-cell apoptosis (b) ($r = 0.56$ and $p < 0.01$) in human autopsy pancreas specimens from subjects with type 2 diabetes (circles) and nondiabetic controls (triangles). inhibited by Congo red [157] or overexpression of the enzyme neprilysin [163] β-cell apoptosis is reduced, suggesting IAPP aggregation is an important mediator of β-cell toxicity. Some, but not all, studies have demonstrated that expression of human IAPP results in an ER stress response [164–166]. However, this appears to be related to the magnitude of IAPP overexpression, and does not occur at physiologic levels of human IAPP, nor does it differ between human islets from individuals with T2DM who do or do not have amyloid deposits [166]. Finally, recent data have shown that human IAPP in its aggregated form is proinflammatory, eliciting cytokine and chemokine production from macrophages/dendritic cells [167,168]. Further, islet IL-1β expression may be increased in conditions of amyloid deposition [112,161,167], suggesting a novel mechanism by which islet amyloid may result in β-cell death.

Islet inflammation

As discussed earlier, inflammation in the islet has long been established as a hallmark of T1DM. Islet infiltration and release of molecules such as proinflammatory cytokines have clearly been implicated in β-cell death in this form of diabetes [169]. In T2DM, the concept that low-grade, chronic inflammation exists, most likely associated with insulin resistance, is a relatively new idea. As this field of research has emerged, so too has the hypothesis that inflammation in the islet may play a role in β-cell death in T2DM [112]. However, this remains a controversial area. Evidence in favor of a role for islet inflammation includes reports of increased islet production of interleukin 1β following chronic high glucose culture of human islets [127]. Islet interleukin 1β production has also been suggested in models of islet amyloid formation [112,161,167]. Activation of signaling pathways associated with the innate immune response (namely toll-like receptors) has been shown to occur in β cells in response to agents such as FFA or lipopolysaccharide [170,171]. This activation can lead to β-cell toxicity and death, suggesting that inflammation may play a role in the demise of the β cell in T2DM.

Summary and future directions

The morphology of the pancreas and pancreatic islet is complex, and disturbances in pancreas and islet volume/arrangement that occur in diabetes are multifactorial. Loss of β cells is a common feature of type 1-, type 2-, and cystic fibrosis-related diabetes. However, the mechanisms that underlie this pathology differ significantly among the various types of diabetes. Our understanding of how β-cell destruction occurs in type 1 and type 2 diabetes has been improved by a large number of studies, but we still have much to learn about how this occurs. Emerging areas of interest include understanding how changes in islet vasculature, innervation, and extracellular matrix contribute to derangements in islet morphology, which may in turn shed new light on the causes of β-cell loss in diabetes.

CHAPTER 6

Insulin gene expression and biosynthesis

Vincent Poitout[1], Roland Stein[2] and Christopher J. Rhodes[3]

Key points

- Glucose stimulates *insulin* gene transcription and insulin mRNA stability.
- Glucose regulates the binding of key transcription factors to the *insulin* gene, notably Pdx-1, MafA, and NeuroD1/Beta2.
- Chronic hyperglycemia and dyslipidemia impair *insulin* gene expression via Pdx-1 and MafA.
- Glucose stimulates translation of the mRNA into proinsulin and processing of proinsulin into mature insulin.
- Proinsulin is processed in the immature granule compartment by successive cleavage at two dibasic sites by the prohormone convertases PC2 and PC1/3.
- Chronic nutrient excess and hyperinsulinemia in type 2 diabetes impose a high secretory demand to the β cell which is not adequately matched by an increase in biosynthetic capacity.

Introduction

The unique property of the pancreatic β cell is its ability to secrete insulin to enable circulating glucose levels to be maintained within a narrow physiologic range, despite wide fluctuations in energy intake and expenditure. It is able to sense the glucose concentration in the extracellular milieu, and adapt its insulin secretion rate via a complex interplay between nutrients, hormones, and neuronal signals. Whereas the minute-to-minute regulation of insulin secretion occurs at the level of exocytosis of pre-formed insulin, adaptation to long-term changes in the environment also involves regulated changes in the transcription rate of the *insulin* gene, translation of the mRNA, and processing of the proinsulin molecule into fully mature insulin. These processes are coordinately regulated by glucose (Figure 6.1) under normal circumstances, and their perturbation leads to β-cell dysfunction and type 2 diabetes.

The first section of this chapter focuses on the structure of the *insulin* gene, normal regulation of its transcription, and dysregulation under pathologic circumstances. In the second section, the successive steps leading from translation of the insulin mRNA molecule to the storage of mature insulin into readily releasable secretory granules are presented, as well as the metabolic regulation of these processes. Space limitations prevent us from exhaustively citing the work of all investigators who contributed to this field. The reader is encouraged to refer to the cited review articles for complete reference lists.

Insulin gene expression

Structure of the *insulin* gene

The *insulin* gene is specifically expressed in pancreatic β cells, although low levels of expression have been detected in the brain [1], the thymus [2], and in the yolk sac during fetal development [3]. The gene's sequence is highly conserved throughout evolution, and is present as a single copy in most species, including humans, where it is located on chromosome 11 between the genes for tyrosine hydroxylase and insulin-like growth factor 2. In rodents, there are two nonallelic *insulin* genes (I and II), resulting from duplication of the original *insulin* II gene [4]. The human *insulin* gene contains three exons and two introns. The first intron is within the 5′-untranslated region, whereas the second intron interrupts the C-peptide coding sequence. The mature preproinsulin mRNA is 446 base pairs (bp) long.

Pancreatic β-cell-enriched gene transcription is controlled by a number of proteins, including both positive-acting islet-enriched transcription factors including Pax6, Pancreatic and duodenal homeobox-1 (Pdx-1), Neurogenic differentiation 1 (NeuroD1/Beta2), and v-maf musculoaponeurotic fibrosarcoma oncogene homolog A (MafA) [5,6], and ubiquitously

Figure 6.1 Various levels of glucose regulation of *insulin* gene expression. Glucose stimulates nuclear translocation of Pdx-1; promotes Pdx-1 and MafA phosphorylation and binding to the insulin promoter; and stimulates transcription of the *insulin* gene, pre-mRNA splicing, translation, and mRNA stability.

distributed transcriptional activators responsive to specific signaling pathways (e.g. activating transcription factor-2 responsive to Ca^{+2} signaling [7]; nuclear factor of activated T cells (NFAT) responsive to Ca^{+2} [8]; kinases such as extracellular-regulated kinases (ERK)1/2 [9]; the transcriptional repressors CCAAT/enhancer-binding protein beta (C/EBPβ) [10] and c-Jun [11]; phosphatases (e.g. calcineurin [12]); and coactivators such as p300 [13]. *Insulin* gene expression is principally controlled by a highly conserved region lying approximately 340 bp upstream of the transcription initiation start, termed the enhancer/promoter control region [14,15]. Considerable progress has been made in defining the many different *cis-* and *trans-*acting factors that ensure precise transcriptional regulation, with the focus here on describing the β-cell-enriched transcription factors most pertinent to metabolically regulated expression, specifically Pdx-1, NeuroD1/Beta2, and MafA.

Pdx-1 is a homeodomain protein that plays a major role in pancreatic β-cell development and function [16,17]. It primarily binds as a monomer to the conserved AT-rich A3 box (-201/-196 bp) and activates insulin transcription, although this protein also appears to act as a repressor in other gene contexts [18]. Pdx-1 is produced early in rodent pancreatic progenitors, and is essential to acinar, ductal, and islet endocrine cell formation [5]. Both homozygous and heterozygous mutations in the PDX-1 gene have been identified in humans, which lead,

respectively, to complete agenesis of the pancreas and a form of maturity-onset diabetes in the young known as MODY 4 [5].

NeuroD1/Beta2 is a basic helix-loop-helix (bHLH) transcription factor, which binds at the conserved *insulin* E1 (-100/-91bp) site in a complex with ubiquitously expressed E-box proteins. *NeuroD1-null* mice die of severe diabetes shortly after birth due to its crucial role in β-cell formation [19]. Moreover, deletion of NeuroD1 specifically in adult β cells *in vivo* causes glucose intolerance and loss of expression of many genes associated with cell maturation and function [20]. Mutations in human *NEUROD1* predisposes one to another form of maturity-onset diabetes in the young, MODY 6 [21], presumably because of its importance in the production and maintenance of fully functional glucose-responsive β cells.

The MafA activator is a basic leucine zipper protein, which binds as a dimer to the conserved *insulin* C1/RIPE3b1 (-118/-107 bp) element. MafA, and the only additional islet synthesized large Maf family member, MafB, are expressed unusually late in pancreatic cell development in relation to other islet-enriched transcription factors. In rodents, MafB is principally present in developing α cells and β cells, and then becomes restricted to α cells soon after birth [22,23]. In contrast, MafA is only found in β cells, with expression first detected during the principal wave of insulin-positive cell production at embryonic day 13.5 in mice [24]. In human islets, MafB is not

only present in α cells but also co-produced with MafA in β cells [25]. A novel role for MafA and MafB in β-cell maturation and function was revealed upon comparing their properties to other islet-enriched transcription factor mutant mice. While islet cell populations are either lost or re-specified in most transcription factor knockout mice [5], the principal defect in *MafB*$^{-/-}$ embryos was reduced insulin and glucagon hormone expression, with no change in endocrine cell numbers or islet cell identity [22,23]. In contrast, islet cell development was unaffected in *MafA*$^{-/-}$ [26] and *MafA*$^{\Delta Panc}$ [27] mice, although glucose-regulated insulin secretion was compromised in adults.

Overall, a highly sophisticated network of transcription factors provides the infrastructure for precisely regulating *insulin* gene transcription, which relies on the cooperative and synergistic interactions between transcription factors and recruited coactivators. Significantly, these factors are also crucial in regulating many other β-cell genes, resulting in a variety of distinct developmental and adult phenotypes in studies of total and conditional transcription factor knockout mice. In the following section, the effect of increasing glucose levels, the most physiologically impactful mediator of β-cell function on Pdx-1, NeuroD1, and MafA will be presented (Figure 6.1).

Physiologic regulation of *insulin* gene expression
Glucose regulation of *insulin* gene transcription factors
Pdx-1 is mainly localized at the nuclear periphery at low glucose concentrations (1–2 mM) in β cells, and becomes phosphorylated and shuttles into the nucleus in response to concentrations stimulating insulin secretion. Many different signaling pathways have been shown to regulate the nucleo-cytoplasmic shuttling and transactivation potential of Pdx-1 under these conditions, including glycogen synthase kinase 3 (GSK3), p38/stress-activated protein kinase, phosphatidylinositol 3-kinase (PI3K), atypical protein kinase C isoforms, mitogen-activated protein kinase (MAPK), and Per-Arnt-Sim (PAS) kinase [6]. Glucose also appears to regulate the interaction of Pdx-1 with various transcriptional coregulators. Thus, Pdx-1 is associated with the histone deacetylases HDAC-1 and HDAC-2 to downregulate *insulin* gene expression under low, non-insulin stimulating glucose concentrations [28]. However, the HDAC-1/2 interaction is prevented at elevated glucose levels, which promotes association with the histone acetyl-transferase p300, hyperacetylation of histone H4, and *insulin* gene transcription [29]. In addition, SUMOylation of Pdx-1 increases its nuclear localization as well as its protein stability and is correlated with an increase in insulin promoter activity [30]. Finally, Pdx-1 contains at least two sites of *O*-GlcNAcylation that increase its DNA binding activity [31,32].

In addition, glucose-induced phosphorylation of NeuroD1 regulates its nuclear localization and transactivation. However, precisely how the regulation is imposed is unknown. Treatment of pancreatic β cells with the MAPK/ERK kinase inhibitor PD98059 blocks nuclear NeuroD1 translocation, conditions that also impact Pdx-1 phosphorylation and *insulin* gene transcription [33]. In addition, high glucose levels induce *O*-GlcNAcylation of NeuroD1 [34], which appears to be important for its translocation into the nucleus. Exactly how these distinct modifications control NeuroD1 activity in islet β cells *in vivo* still needs to be explored.

Increased MafA protein and DNA activity regulates glucose-dependent *insulin* gene transcription, with phosphorylation modulating *insulin* enhancer binding [35]. In addition, the transactivation potential of MafA is potentiated by GSK3-mediated phosphorylation within the N-terminal region which allows recruitment of the P/CAF coactivator [36]. However, precisely how phosphorylation regulates these properties of MafA remains to be determined.

Glucose regulation of insulin mRNA stability
In addition to its major effects on transcription of the insulin promoter, glucose markedly stabilizes preproinsulin mRNA. Indeed, the half-life of the message has been estimated to increase from 29 hours to 77 hours when switched from low to high glucose. Two elements located in the 3′-untranslated region of the mRNA molecule have been proposed as mediators of the glucose-stabilizing effect, the conserved UUGAA sequence and the pyrimidine-rich sequence (insPRS) [37]. Stabilization appears to involve binding of a polypyrimidine tract-binding (PTB) protein to the insPRS, as binding was induced by glucose and prevented upon mutating the core PTB binding site.

Glucose regulation of the *insulin* gene *in vivo*
Variations in the amount of insulin mRNA at any given time represent the net effect of metabolic, hormonal, and neuronal stimuli on *insulin* gene transcription and mRNA stability. From the *in vitro* effects described earlier, it is predicted that increases in blood glucose should rapidly elevate preproinsulin mRNA levels in the endocrine pancreas (due to rapid stimulation of transcription), whereas a decrease in blood glucose would be followed by a slow decline in preproinsulin mRNA levels (due to reduced transcription and the long half-life of the message). Indeed, early studies in rats showed that 4 days of starvation are necessary to detect significant decreases in preproinsulin mRNA, which returned to basal values only 6 hours after re-feeding [38] or 12 hours after glucose injection [39]. The delay in the disappearance of the message upon fasting appears to be directly due to the stability of the mRNA, as insulin-induced hypoglycemia is followed by a rapid (2-hour) decrease in the level of precursors for insulin mRNA [40].

An additional level of complexity in the regulation of *insulin* gene expression *in vivo* is the potential interaction between β cells and non-β (i.e., α, δ, and PP) cells within the intact islet. Indeed, it is known that individual β cells behave differently from one another in terms of insulin secretion than in the context of the islet [41], a phenomenon which has also been demonstrated at the level of *insulin* gene transcription [42]. Thus, the global response measured in an entire islet represents the integration of

the individual responses. This fact should be kept in mind when interpreting experiments performed in clonal cell lines, which lack the level of regulation provided by islet architecture and the neighboring non-β cells.

Regulation of *insulin* gene expression by glucagon-like peptide-1 (GLP-1)

GLP-1 is an incretin hormone which strongly potentiates glucose-induced insulin secretion and is the target of a number of type 2 diabetes drugs [43]. Most of the biologic effects of GLP-1 are mediated by its G protein-coupled receptor expressed on the β-cell surface [44]. GLP-1 stimulates *insulin* gene expression by various mechanisms. First, it directly activates the cyclic-AMP (cAMP) response element (CRE) within the 5′-proximal control sequences of the *insulin* gene, by a mechanism which seems at least partly independent from protein kinase A activation [45]. Second, it can augment the glucose-stimulated binding activity of Pdx-1 [46]. Third, it can stimulate transcription of the PDX-1 gene (the promoter of which also contains a CRE) [47]. Fourth, GLP-1 potentiates glucose-induced *insulin* gene transcription by activating NFAT (of which there are three binding sites on the rat insulin I promoter) via calcium/calmodulin-dependent protein phosphatase 2B (calcineurin) activation in response to a rise in intracellular calcium [48].

Physiologic inhibitors of *insulin* gene expression

Several physiologic inhibitors of insulin secretion also impair expression. Epinephrine and somatostatin, two hormones acting through G protein-coupled receptors and known inhibitors of insulin release [49], also inhibit the rate of *insulin* gene transcription [50]. In addition, somatostatin decreases the stability of insulin mRNA [51]. Glucagon, a key hormone in the counterregulatory response to hypoglycemia *in vivo*, stimulates expression of the inducible cAMP early repressor, which inhibits *insulin* gene transcription [52]. Finally, the adipocyte-secreted hormone leptin decreases *insulin* gene expression [53]. Thus, physiologic modulators of insulin secretion coordinately inhibit *insulin* gene expression, thereby ensuring that the long-term biosynthetic rate of insulin matches the secretory demand.

Short-term regulation of *insulin* gene expression by insulin

Whether insulin has a functionally relevant role in the regulation of insulin transcription and biosynthesis remains a debated issue [54,55]. Based on the observation that a rapid (within minutes) transcriptional response to glucose in insulin-secreting cells was mimicked by depolarizing agents and exogenous insulin and was suppressed by inhibiting insulin release or the PI3 kinase pathway, it was proposed that insulin acts in an autocrine manner to stimulate *insulin* gene transcription by binding to the insulin receptor [54]. However, subsequent studies have failed to detect significant changes in preproinsulin mRNA levels upon short-term exposure to glucose and the physiologic relevance of an autocrine positive feedback on the β cell has been questioned [55].

Dysregulation of the *insulin* gene

There is convincing evidence that abnormalities in *insulin* gene sequence or function play a role in pancreatic β-cell dysfunction in type 2 diabetes. Abnormalities in the *insulin* gene structure consist of rare control region mutations, while *insulin* gene expression appears to be reduced by metabolic conditions associated with the diabetic state.

Polymorphisms of the *insulin* gene

The diabetes susceptibility gene IDDM2 has been mapped to the insulin variable number of tandem repeats (VNTR), a highly polymorphic region located 360 bp upstream of the transcription initiation site in the human *insulin* gene [56]. VNTRs are classified as class I, II, or III, depending on the number of tandem repeats. Whereas the short class I VNTR gene predisposes to type 1 diabetes, the long class III allele is protective. Precisely how VNTR polymorphisms confer susceptibility to or protection from diabetes remains uncertain, although recent evidence clearly suggest that the VNTR determines expression levels of insulin in the thymus and, in turn, the numbers of insulin-specific autoreactive T cells [56].

Glucotoxicity and the *insulin* gene

The glucotoxicity hypothesis proposes that chronic hyperglycemia is deleterious to β-cell function by contributing to the deterioration of insulin secretion [57]. These adverse effects of chronically elevated glucose levels include, but are not limited to, impairment of *insulin* gene expression in insulin-secreting cells, isolated rat and human islets, and animal models of diabetes [58]. The molecular mechanisms underlying glucotoxicity at the *insulin* gene involve decreased expression of Pdx-1 and MafA (Figure 6.2), as well as increased expression of C/EBPβ which directly binds the NeuroD1/Beta2, thereby preventing formation of the NeuroD1/Beta2:E47 activator complex required for insulin E1 stimulation [59]. In addition, binding of a C/EBPβ-NFAT complex at the A2C1 element of the insulin promoter under glucotoxicity prevents the formation of the MafA-NFAT complex at that site required for normal glucose stimulation of insulin transcription [60].

The biochemical mechanisms whereby chronically elevated glucose impairs *insulin* gene expression have received considerable attention in the past few years. The prevailing hypothesis is that high glucose induces the excessive production of reactive oxygen species (ROS) and the formation of advanced glycation end-products (AGE) [61,62]. This hypothesis is supported by *in vivo* observations. For example, treatment of Zucker diabetic fatty (ZDF) rats with the antioxidant N-acetylcysteine normalizes plasma glucose levels and restores insulin secretion, insulin content, and preproinsulin mRNA levels [63]. Similarly, over-expression of glutathione peroxidase-1 in *db/db* mice reversed hyperglycemia and restored MafA nuclear localization [64].
Figure 6.2 Molecular mechanisms of action for glucotoxicity and glucolipotoxicity at the level of *insulin* gene expression. Under physiologic conditions, MafA and Pdx-1 are two critically important regulators of the insulin promoter, and respectively bind to the C elements and the A boxes (upper panel). Glucotoxicity greatly diminishes protein levels of Pdx-1 and MafA, the former through a posttranscriptional mechanism and the latter through a posttranslational mechanism. These abnormalities lead to decreased insulin mRNA, insulin content, and glucose-induced insulin secretion, and are reversible only in the early stages of glucose toxicity (middle panel). Under glucolipotoxic conditions, MafA expression is inhibited, whereas Pdx-1 is affected at the post posttranslational level in its ability to translocate to the nucleus. This results in decreased *insulin* gene expression (lower panel). Source: Poitout 2008 [58]. Reproduced with permission of The Endocrine Society.

Oxidative stress-mediated impairment in Pdx-1 binding activity is prevented by overexpression of a dominant-negative c-*jun* N-terminal kinase (JNK), and is mimicked by overexpression of wild-type JNK [65]. In addition, chronic exposure to elevated glucose levels may lead to dedifferentiation with loss of genes associated with β-cell function and overexpression of genes normally repressed in differentiated β cells [66,67]. For instance, the c-*myc* transcription factor is upregulated in diabetic islets [68] and is induced by high glucose in normal islets [69]. In turn, c-*myc* can inhibit *insulin* gene transcription [70] by competing for NeuroD1/Beta2 binding at the E-box [71].

Endoplasmic reticulum (ER) stress has also been proposed to contribute to the mechanisms of glucotoxicity independently from oxidative stress [72]. However, alleviation of ER stress by chemical chaperones in glucose-cultured islets improves insulin secretion but not intracellular insulin content, suggesting that ER stress may be involved in defective insulin secretion but not impaired insulin biosynthesis under glucotoxic conditions [73].

Glucolipotoxicity and the *insulin* gene
Like chronic hyperglycemia, hyperlipidemia has been proposed to contribute to β-cell dysfunction in type 2 diabetes [74]. Most of the deleterious effects of chronically elevated lipid levels on the β cell require the concomitant presence of hyperglycemia, a phenomenon referred to as glucolipotoxicity [75]. Amongst its many functional consequences, glucolipotoxicity impairs *insulin* gene expression via a transcriptional mechanism that involves *de novo* synthesis of ceramide and defective function of Pdx-1 and MafA [76,77]. Importantly, defective Pdx-1 function and *insulin* gene expression are also observed in an *in vivo* model of glucolipotoxicity in rats following a 72-h infusion of glucose and Intralipid, a lipid emulsion which raises circulating

fatty acid levels when co-infused with heparin [78,79]. It is interesting that glucotoxicity and glucolipotoxicity both affect Pdx-1 and MafA function, albeit by different mechanisms: glucotoxicity alters Pdx-1 mRNA expression [80] and MafA nuclear localization [64], while in glucolipotoxicity Pdx-1 is retained in the cytosolic compartment while MafA mRNA expression is reduced [77] (Figure 6.2).

How *de novo* ceramide synthesis from palmitate, in the presence of elevated glucose, alters the function of Pdx-1 and MafA and leads to defective *insulin* gene expression remains unknown. One possible candidate is the serine/threonine kinase PAS kinase, which regulates glucose-induced *insulin* gene transcription [81]. In insulin-secreting cells and isolated islets, we observed that overexpression of PAS kinase protects from the negative effects of palmitate on the *insulin* gene [82]. Recent data suggest that this could be mediated by PAS kinase inactivation of GSK3β (via phosphorylation at Ser9) and alleviation of GSK3β-mediated serine phosphorylation of Pdx-1 and proteasomal degradation ([83] and M. Semache, G. Fontés, S. Fogarty, C. Kikani, M. B. Chawki, J. Rutter and V. Poitout, unpublished data). A second candidate mediator of ceramide inhibition of the *insulin* gene is c-*jun* N-terminal kinase (JNK). In support of this possibility, palmitate was shown to activate JNK in β cells which results in a decrease in *insulin* gene transcription [84].

Relevance to human type 2 diabetes

Recent studies in human islets support the notion that defective *insulin* gene expression may play a role in human type 2 diabetes. First, in islets isolated from pancreata of 13 type 2 diabetic cadaveric organ donors high levels of oxidative stress markers as well as low levels of glucose-induced insulin secretion, reduced insulin mRNA, but increased levels of Pdx-1 and FOXO1 mRNAs have been observed [85]. Second, nuclear expression of MafA is decreased in human diabetic islets [86]. Third, DNA methylation of the insulin promoter is increased in type 2 diabetic patients and correlates negatively with *insulin* gene expression and positively with hemoglobin A1c levels [87].

Insulin biosynthesis

Introduction

The previous section outlines that *insulin* gene transcription is a highly controlled process. The product of this process, preproinsulin mRNA, is unusually stable in pancreatic β cells and it is further stabilized as glucose concentrations increase [37]. As such, there is normally an abundant source of preproinsulin mRNA in the β-cell cytosol available for translation. Actually, it is the specific regulation of preproinsulin mRNA translation that is the *predominant* control mechanism for insulin production in the β cell under normal circumstances. This enables the β cell to rapidly replenish insulin stores back to optimal levels, after they have been depleted by stimulated insulin secretion, and is more economic energy-wise to the β cell, since translational control of insulin production bypasses the need for *insulin* gene transcription and preproinsulin mRNA maturation.

Structure of the insulin molecule

The primary structure A- and B-chain of insulin itself has been known for close to 50 years [88]. However, it was not until at least 10 years after this discovery that it was realized insulin is actually synthesized as a single polypeptide chain precursor molecule, preproinsulin (Figure 6.3) [88]. The N-terminal signal peptide (24 amino acids) is cleaved cotranslationally to yield proinsulin. The proinsulin molecule is a 12-kDa single chain polypeptide that encompasses the B-chain (30 amino acids) and the A-chain (21 amino acids) of insulin joined by the connecting peptide, C-peptide (Figure 6.3). Proinsulin to insulin conversion occurs by cleavage at two dibasic amino acids sequences by the B-chain/C-peptide and C-peptide/A-chain junctions to release the C-peptide moiety yielding the insulin molecule with the two independent disulphide-linked A- and B-chains correctly aligned [88].

Proinsulin biosynthesis: translation and translocation

Essentially, translation of preproinsulin mRNA to preproinsulin protein occurs in a fashion typical of most eukaryotic mRNAs destined to enter the cell's secretory pathway [88–90]. During the translation process, the emerging signal sequence of preproinsulin binds the signal recognition particle (SRP) that then docks to the SRP-receptor, which is an integral ER membrane protein. This locates the preproinsulin mRNA/ribosomal translational complex to the ER, which is the major site of proinsulin biosynthesis in the β cell. As SRP binds to the SRP receptor, the nascent signal peptide of the newly forming preproinsulin dissociates and is transferred to another ER integral membrane protein, the signal sequence receptor (SSR). SSR is part of a "translocation pore" that facilitates transport of the newly forming preproinsulin polypeptide across the ER membrane into the ER lumen, marking the entrance of the newly synthesized preproinsulin into the β-cell's secretory pathway. The signal peptide is cleaved by another RER protein, the signal peptidase, resulting in the nascent proinsulin molecule located to the ER lumen. There, the proinsulin molecule undergoes appropriate folding, assisted by the molecular chaperons and formation of disulfide bonds catalyzed by ER disulfide isomerase activity [88].

Proinsulin biosynthesis: effectors and stimulus-response coupling mechanisms

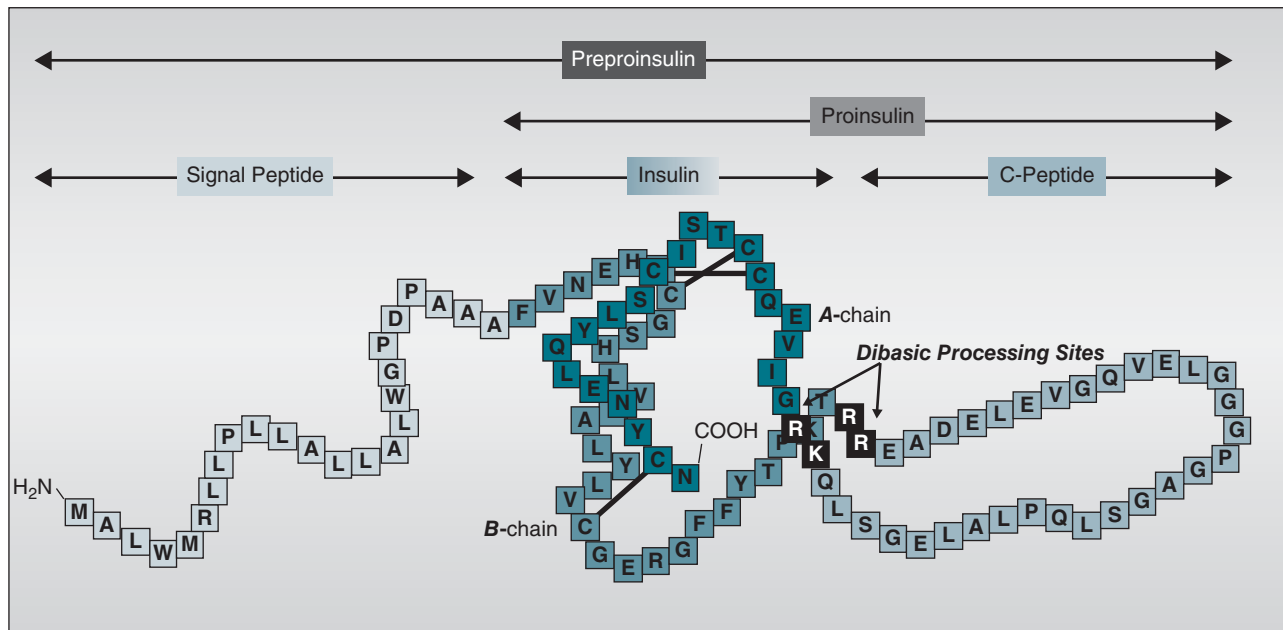
Proinsulin biosynthesis is translationally controlled by certain nutrients, neurotransmitters, and hormones, but glucose is the most physiologically relevant [91]. This translational control response to glucose is rapid. Significant glucose-induced proinsulin biosynthesis can be observed after a 20–30-min lag period that reaches a maximum rate (~20–30-fold increase above basal) by 60 min [91]. Of the peptide hormones that stimulate


Figure 6.3 Primary structure of human preproinsulin indicating the N-terminal signal peptide, followed by the insulin B-chain, the connecting-peptide (C-peptide), and then the C-terminal insulin A-chain. The two dibasic proteolytic conversion sites and the endoproteases that cleave at these are also indicated (PC-3 at Arg[31], Arg[32]; and PC-2 at Lys[64], Arg[65]). The signal peptide + insulin + C-peptide moieties comprise preproinsulin, and the insulin + C-peptide moieties comprise proinsulin.

proinsulin biosynthesis, perhaps the incretins, GLP-1 and GIP, are the most physiologically relevant. GLP-1/GIP do not increase proinsulin biosynthesis translation in their own right, but potentiate glucose-induced proinsulin biosynthesis as they do glucose-induced insulin secretion [92]. Epinepherine is also worthy of mention for specifically inhibiting glucose-induced proinsulin biosynthesis as it does glucose-induced insulin secretion [91].

Unlike that for glucose-induced insulin secretion, the secondary signals that lead to an increase in proinsulin biosynthesis are less well defined. Glucose metabolism is required for glucose-induction of both proinsulin biosynthesis and insulin secretion, but several lines of evidence indicate that the stimulus-response coupling mechanism for these β-cell functions are quite distinct [91,92]. For example, sulfonylureas stimulate and diazoxides inhibit glucose-induced insulin secretion, but these compounds have no effect on glucose-induced proinsulin biosynthesis indicating the signal transduction mechanism for regulating proinsulin biosynthesis is independent of the K_{ATP}-channel and increase in cytosolic Ca^{2+}, unlike that for glucose-stimulated insulin secretion [91,92]. Somatostatin is a potent inhibitor of insulin secretion, but has no effect on proinsulin biosynthesis [91,92]. Long-chain fatty acids, when applied acutely, are marked potentiators of glucose-induced insulin secretion, but if anything modestly inhibit glucose-induced proinsulin biosynthesis [91,92]. It has been indicated that a secondary signal for glucose-induced proinsulin biosynthesis might be mitochondrial export of succinate and cytosolic accumulation of succinyl-CoA, but

what lies downstream of succinate/ succinyl-CoA to specifically upregulate preproinsulin mRNA translational machinery requires further investigation.

Proinsulin biosynthesis: translational control mechanism

Glucose modestly increases general protein synthesis in the β cell ~1.5–2-fold. However, the effect of glucose on proinsulin synthesis translation is much greater, and can reach ≥10-fold stimulation above basal [91,92]. This indicates a *specific* effect of glucose on translational control of proinsulin biosynthesis. Such specific control of glucose-induced proinsulin biosynthesis in the β cell, resides in *cis*-elements in the 5′- and 3′-untranslated regions (UTRs) of preproinsulin mRNA itself [92]. In the 3′-UTR of preproinsulin mRNA, just downstream of the polyadenylation signal, there is a highly conserved primary sequence containing a UUGAA *cis*-element core, that has been reported to be involved in glucose-regulated preproinsulin mRNA stability in addition to the pyrimidine-rich sequence (insPRS) [37,92] (see earlier). There is some degree of cooperativity between the preproinsulin mRNA 5′- and 3′-UTRs for the *specific* glucose-induced translational control of proinsulin biosynthesis, but it appears that the 5′-UTR preproinsulin mRNA has the major influence [92]. There is also a conserved *cis*-element that is required for glucose-induced translational control of proinsulin biosynthesis, named ppIGE (for preproinsulin glucose element) [92]. The ppIGE has a highly conserved ppIGE palindromic core of $GUCx_nCUG$ or $GUUx_nUUG$ (where $n \leq 4$ bases). A cytosolic protein *trans*-acting factor

(ppIE-BP) binds to this translational control ppIGE *cis*-element of preproinsulin mRNA in a glucose-dependent manner, but the identity of the ppIGE-BP has yet to be revealed [92]. It should be noted that proinsulin is only one of a small subset of β-cell proteins (∼50 in all) [92] whose biosynthesis is regulated by glucose at the translational level. These are mostly β-granule proteins, including the proinsulin processing endopeptidases, PC2 and PC1/3 [92]. Indeed, the ppIGE is also conserved in the 5′-UTR of the majority insulin secretory granule proteins' mRNAs, and thus, the glucose-induced specific translational control of proinsulin biosynthesis and that for insulin secretory granules can be coordinated and is the principal control mechanism for insulin secretory biogenesis in β cells [92]. The glucose-induced translational control of the proinsulin processing endopeptidases, proPC2 and proPC3, provides a means whereby proinsulin conversion is not compromised upon increased proinsulin biosynthesis [92].

Transport of proinsulin from the ER to Golgi apparatus

After proinsulin is translocated into the lumen of the ER, it is then delivered in transport "COP-coated vesicles" to the *cis*-Golgi apparatus [93] (Figure 6.4). Up until relatively recently, it was thought that newly synthesized proinsulin was passed from the *cis*-Golgi network "stack" via the *medial-* to the *trans*-stack of the Golgi apparatus stacks in "COP"-coated vesicles, but a landmark study conducted in β cells using electron microscope tomography showed that the Golgi apparatus is actually one continuous organellar compartment, and not a series of stacks [94]. As such, newly synthesized proinsulin traverses through the lumen of the β cell's Golgi apparatus to the *trans*-Golgi network (TGN) [94], where it accumulates in clathrin-coated regions [93]. This is the site of secretory granule biogenesis (Figure 6.4). The means by which newly synthesized proinsulin (and other select proteins destined to the β granule), is specifically targeted to sites of β-granule biogenesis in the TGN remains a matter of debate [95]. However, it is known to be a highly efficient process, with >99% efficient of newly synthesized proinsulin sorted to the β granule and regulated secretory pathway under normal conditions [91,95].

Generally, analogous to other neuroendocrine cells, the process of β-granule biogenesis should also require other factors including intraluminal acidic pH 6.5, Ca^{2+}, ATP, GTP-hydrolysis cytosolic proteins and perhaps protein tyrosine phosphorylation [88,91,93,95]. Although β-granule biogenesis occurs in limited clathrin-coated regions of the TGN [93], the role that clathrin itself plays is unclear although is likely involved in the process of a newly formed immature β granule "budding off" the TGN. An immature β granule then undergoes a maturation process [93,95]. Maturation of β granules involves proinsulin conversion, progressive intragranular acidification, loss of the clathrin-coated regions, and formation of hexameric insulin crystals [91,93]. Acidification provides the correct intragranular pH (pH 5.0–5.5) for proinsulin processing to proceed [91], and optimal insulin crystal formation around insulin's isoelectric point (pKi 5.3) [88]. Delivery of newly synthesized proinsulin to an immature β granule occurs around 30–40 min posttranslation where proinsulin processing begins and is >90% completed ∼3 h later [91,93] (Figure 6.4).

Proteolytic enzymes of proinsulin conversion

The major site for processing of proinsulin to biologically active insulin is the immature secretory granule compartment of the β cell [91,93] (Figure 6.4). Production of insulin (and C-peptide) occurs via limited proteolysis of the proinsulin precursor molecule, which is catalyzed by two Ca^{2+}-dependent endopeptidases, PC2 and PC1/3 and a Ni^{2+}-dependent exopeptidase, CP-H [88,91]. There are two dibasic sites on the human proinsulin molecule: Arg^{31}, Arg^{32} and Lys^{64}, Arg^{65}, that signal limited endoproteolytic cleavage of proinsulin to excise the C-peptide moiety and to generate insulin with its disulphide-linked A- and B-chains correctly aligned (Figure 6.3). Endoproteolytic peptide bond cleavage of proinsulin occurs on the carboxylic side of the Arg^{31}, Arg^{32} or Lys^{64}, Arg^{65}, followed by rapid and specific exopeptidic removal of the newly exposed basic amino acids by CP-H [88,91]. The two distinct β-granule proinsulin-processing endopeptidase activities were originally discovered as Ca^{2+}-dependent with an acidic pH optimum and were later identified as the PC1/3 and PC2 endopeptidase genes [88,91].

A scheme of proinsulin conversion is illustrated in Figure 6.5. Proinsulin conversion could occur by two possible routes. Either PC2 first cleaves on the carboxylic side of Lys^{64}-Arg^{65} to yield a split 65,66 proinsulin intermediate, followed by CP-H trimming of the newly exposed lysine and arginine residues to yield des 64,65 proinsulin. Then PC1/3 can then cleave des 64,65 proinsulin at Arg^{31}, Arg^{32}, which together with CP-H trimming of the exposed arginine residues, yields insulin and C-peptide (Figure 6.5). Alternatively, PC1/3 first could cleave at the carboxylic side of Arg^{31}, Arg^{32} to yield a split 32,33 proinsulin intermediate, followed by CP-H trimming of the revealed arginine residues to yield des 31,32 proinsulin. PC2 can then cleave des 32,33 proinsulin at Lys^{64}-Arg^{65}, which together with CP-H trimming of the lysine and arginine residues, yields insulin and C-peptide (Figure 6.5). However, PC2 has a much stronger preference for the des 31,32 proinsulin substrate than proinsulin, whereas PC1/3 has an equivalent preference for proinsulin or des 64,65 proinsulin substrates [88,91]. As such, in humans, the sequential processing of proinsulin via des 31,32 proinsulin is the predominant route, where PC1/3 cleaves intact proinsulin first, followed by PC2 cleavage of des 31,32 proinsulin (Figure 6.5). This is consistent with the presence of the des 31,32 proinsulin conversion intermediates in the human circulation but negligible levels of des 64,65 proinsulin [91].

PC2, PC1/3 and CP-H are expressed in most neuroendocrine cells where they are involved in posttranslational processing of other prohormone precursors [88]. The role of these proteolytic enzymes in proinsulin conversion has been substantiated in
Figure 6.4 Cell biology of proinsulin trafficking and processing. The site of preproinsulin biosynthesis is on the ribosomes of the ER. The signal peptide is cleaved co-translationally enabling proinsulin translocation into the ER lumen. The newly synthesized proinsulin is then transported to the *cis*-Golgi and transported though the stacks of the *medial*-and *trans*-Golgi to clathrin-coated regions of the *trans*-Golgi network (TGN). Immature β granules bud off the TGN which is the major site of proinsulin conversion (~30 min posttranslationally). Proinsulin conversion proceeds as a β granule matures. Mature granules form the intracellular insulin storage compartment of the β cells and do not undergo Ca^{2+}-dependent exocytosis unless triggered by an appropriate stimulus. The left panel indicates the intracellular compartments in which proinsulin is sequentially transported through, and the right panel indicates the kinetics of the preproinsulin biosynthetic/processing/secretory process in these compartments.

various gene-deletion studies. PC2, PC1/3 or CP-H deficiencies render multiple endocrine deficiencies. PC2 knockout mice have defective proinsulin processing with increased levels of the split proinsulin conversion intermediate des 31,32 proinsulin, consistent with PC2 preferentially cleaving at the Lys^{64}, Arg^{65} site on proinsulin, and the preferred sequential proinsulin processing route [88] (Figure 6.3). Indeed, PC2 *null* mice have a polyendocrine phenotype the most obvious being fasting hypoglycemia and glucose intolerance due to a deficiency of circulating glucagon levels rather than increased insulin levels [88]. A human mutation of both PC1/3 alleles exists,

which results in negligible PC1/3 activity [88]. This generates a complicated phenotype of multiple endocrine disorders due to general abnormal prohormone processing, one of which is very low insulin levels and high proinsulin levels, together with abnormal glucose homeostasis, consistent with defective proinsulin processing [88]. A very similar phenotype is found in the PC1/3 *null* transgenic mouse model [88]. Finally, the obese *Fat/Fat* mice have been found to have a mutation in the CP-H gene resulting in negligible CP-H activity [91]. These CP-H *null* animals are hyperproinsulinemic, suggesting that CP-H trimming off of basic amino acids after PC2 and
Figure 6.5 Enzymatic proteolytic conversion of proinsulin. There are two potential pathways of proteolytic conversion of proinsulin to insulin. Either PC2 first cleaves proinsulin at Lys^{64}-Arg^{65} to yield split 65,66 proinsulin, followed by CP-H trimming of the newly exposed lysine and arginine residues to yield des 64,65 proinsulin. PC3 can then cleaves des 64,65 proinsulin at Arg^{31}, Arg^{32}, which together with CP-H trimming of the exposed arginine residues, yields insulin and C-peptide. Alternatively, PC3 cleaves at Arg^{31}, Arg^{32} to yield a split 32,33 proinsulin, followed by CP-H trimming of the revealed arginine residues yields des 31,32 proinsulin. PC2 can then cleave des 32,33 proinsulin at Lys^{64}-Arg^{65}, which together with CP-H trimming of the lysine and arginine residues, yields insulin and C-peptide. In human β cells, the route via des 31,32 proinsulin predominates as illustrated by the larger size of this pathway.

PC1/3 endopeptidic cleavage accelerates proinsulin proteolytic maturation through to insulin [91]. Moreover di-arginyl insulin (that has >50% reduced biological activity) rather than insulin is produced indicating the role that CP-H plays in trimming basic amino acids during the proinsulin conversion process [91].

Regulation of proinsulin conversion

PC2 and PC1/3 are Ca^{2+}-dependent enzyme activities with an acidic pH 5–5.5 optimum [91]. Fortunately, the β granule contains an intraorganellar environment of 1–10 mM free Ca^{2+} and acidic pH 5.5, which ideally suits the requirements for optimal PC2, PC1/3 and CP-H activities within this organelle. This also ensures that insulin is produced mainly in the intracellular β-granule compartment in which it is stored [91]. To render PC2 and PC1/3 fully active for proinsulin processing in a newly formed β granule, it follows that activation of the proton-pumping ATPase and Ca^{2+}-translocation proteins [91] are key regulatory events to control proinsulin conversion.

Both PC2 and PC1/3 are initially synthesized as preproprotein precursor molecules themselves, with the "pre" signal peptide region enabling translocation into the RER lumen during translation as with the signal peptide region of proinsulin (see

earlier). ProPC2 and proPC1/3 are transported to β granules along with their proinsulin substrate in the β cell's secretory pathway and undergo maturation beginning in the TGN [91]. However, unlike proinsulin, proPC2 and proPC1/3 are thought to be accompanied by individual chaperon molecules, 7B2 and proSAAS, respectively, that specifically inhibit these endopeptidases' activity [91]. Proteolytic cleavage of 7B2 by PC2 in the TGN/immature β-granule compartment alleviates the inhibition on proPC2 promoting its maturation and activation to mature PC2. Indeed, 7B2 has an important role in controlling PC2 activity *in vivo*. The 7B2 knockout mouse has multiple neuroendocrine disorders, similar yet more severe than the PC2 *null* mouse [91]. In contrast, the role of proSAAS in regulating proinsulin processing is doubtful, since proSAAS *null* mice have normal insulin production and proSAAS is not highly expressed in β cells [96,97].

As previously indicated, the biosynthesis of proPC2 and proPC1/3 is stimulated predominately at a translational level coordinately with that of proinsulin [88,91,92]. In the long term (>12 h), glucose also regulates PC2 and PC1/3 gene transcription in parallel with the preproinsulin gene [91]. Thus, it seems that proinsulin conversion is adaptable to changes in glucose by coordinate regulation of the endopeptidases that catalyze processing [91,92].

The mature β-granule storage pool

A mature β granule is retained from anywhere between a few hours to several days, awaiting transport to the β cell's plasma membrane and exocytosis under stimulatory conditions, characteristic of a regulated secretory pathway [88,92] (Figure 6.4). It should be noted that under normal conditions, the storage compartment of insulin in mature β granules far exceeds the compartment undergoing transport/exocytosis, so that during a 1-h stimulation by glucose only ~1–2% of the insulin content of a primary islet β cell is secreted [92]. The insulin content of a β cell is kept at a relatively constant level under normal physiologic conditions where secreted insulin is rapidly replaced at the biosynthetic level. However, in the long term there is also an additional regulatory component that maintains insulin stores at optimal levels, via insulin degradation [92]. The half-life of a β granule is several days, but if it is not used for exocytosis it is eventually degraded by fusion with lysosomal compartments by autophagy (also known previously as *crinophagy*) [92].

Dysfunctional proinsulin processing in diabetes

In type 2 diabetes where there is hyperinsulinemia to compensate for peripheral insulin resistance, an increased proportion of the secreted insulin is actually proinsulin or split proinsulin conversion intermediates (mostly des 31,32 proinsulin) so that it is also a hyperproinsulinemic state [91]. It is possible that genetic defects in the proinsulin conversion enzyme genes or the *insulin* gene itself hamper proinsulin conversion, resulting in an increased proportion of proinsulin secreted. However, such genetic mutations are very rare, yet hyperproinsulinemia is a common trait of type 2 diabetes [91]. As such, an increased proportion of secreted proinsulin likely occurs as a consequence of β-cell secretory dysfunction in type 2 diabetes [91].

In common *obesity-linked* type 2 diabetes there is chronic hyperglycemia and dyslipidemia [88,91,92]. As a consequence, the β cell is working very hard, with both proinsulin synthesis and insulin secretion are upregulated in an attempt to compensate for peripheral insulin resistance. Normally in β cells there is preferential exocytosis of newly formed β granules, but under such chronic stimulation from hyperglycemia/hyperlipidemia newly synthesized proinsulin is not retained long enough to be fully converted to insulin and C-peptide, and as a consequence a greater proportion of proinsulin (as well as des 31,32 proinsulin) is secreted [88,91]. It should also be noted that chronic dyslipidemia adversely affects secretory capacity of β cells. Elevated fatty acid levels increase the amount of insulin secreted from the β cell, but in contrast, fatty acids modestly inhibit glucose-induced proinsulin biosynthesis, which in turn markedly decreases insulin content of islet β cells *in vivo* [92]. A similar situation might also be envisaged with the prolonged use of sulfonylureas, which though potent inducers of insulin secretion, do not stimulate proinsulin synthesis and decrease insulin content [92], thus also reducing the insulin secretory capacity of the β cell. In general, the chronic hyperglycemia and dyslipidemia in *obesity-linked* type 2 diabetes are constantly making the β cell work harder to produce sufficient insulin to compensate for increased metabolic load and peripheral insulin resistance [91,92]. But in the long run this eventually leads to β-cell dysfunction of which the hyperproinsulinemia is symptomatic. Interestingly, if the β cell in type 2 diabetes patients is allowed to rest, the β-cell secretory dysfunction *in vivo* is reduced. This emphasizes the importance of protecting β-cell mass and function in the treatment of *obesity-linked* type 2 diabetes [88,91,92].

Key points

- Pancreatic β cells secrete insulin in response to glucose.
- Glucose-induced insulin secretion (GIIS) requires metabolism of glucose.
- Glucose generates both triggering and amplifying signals.
- GIIS is modulated by hormones, neurotransmitters, and nutrients.
- Glucose induces insulin secretion in a biphasic manner.
- There are different pools of insulin granules.
- Insulin granule exocytosis depends on soluble N-ethylmaleimide-sensitive factor attachment protein receptors (SNAREs) and their associated molecules.
- G-protein-coupled receptors are involved in modulation of GIIS.
- β-Cell dysfunction is associated with the development of diabetes.

Introduction

In pancreatic β cells, glucose metabolism is essential for the regulation of insulin secretion. Glucose is taken up by glucose transporters and metabolized to generate adenosine triphosphate (ATP), which is the main driver of glucose-induced insulin secretion (GIIS). Increased cytosolic ATP causes closure of ATP-sensitive K^+ (K_{ATP}) channels, depolarizing the plasma membrane, leading to the opening of voltage-dependent Ca^{2+} channels (VDCCs), which allows Ca^{2+} influx. The resultant rise in intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) induces exocytosis of insulin granules in the triggering pathway of insulin secretion (Figure 7.1). In addition, other signals generated by glucose amplify insulin secretion. Lipid metabolism is also involved in GIIS by interacting with glucose metabolism.

Glucose induces insulin secretion in a biphasic manner: an initial component (1st phase) develops rapidly but lasts only a few minutes, and is followed by a sustained component (2nd phase). Pancreatic β cells contain at least two pools of insulin secretory granules that differ in release competence: a reserve pool (RP) that accounts for the vast majority of granules, and a readily releasable pool (RRP) that accounts for the remaining <5%. Although the prevailing hypothesis is that release of predocked granules accounts for the 1st phase and a subsequent supply of new granules mobilized for release accounts for the 2nd phase of GIIS, recent studies show that both phases involve granules that are located some distance from plasma membrane. Hormonal and neural inputs to the β cells are also important for modulating GIIS.

β-Cell metabolism

Glucose sensing glycolysis

The most prominent feature of pancreatic β cells is secretion of insulin in response to changes in the physiologic concentration of extracellular (blood) glucose, the cells possessing the capacity to sense circulating glucose levels. Glucose is transported into the β cells through facilitated glucose transporters and then is promptly phosphorylated by glucokinase in the glycolytic pathway. In rodents, the major glucose transporter is GLUT2, which is a high-capacity, low-affinity glucose transporter isoform. Although GLUT2 is the major glucose transporter in pancreatic β cells in rodents, GLUT1 is predominantly expressed in human β cells [1]. On the other hand, the glucose-phosphorylating enzyme glucokinase (hexokinase IV: a high *K*m isoform of hexokinase) catalyzes the formation of glucose-6-phosphate from glucose without allosteric inhibition of the product. As glucokinase determines the rate of glycolysis, it is considered to be the molecular glucose sensor for insulin secretion in pancreatic β cells [2]. Indeed, overexpression of hexokinase shifts glucose sensitivity in a mouse pancreatic β-cell line [3] and mutations in the glucokinase gene can cause diabetes [4]. Phosphorylated glucose is then metabolized to produce pyruvate, the end product of glycolysis. As the expression of lactate dehydrogenase (LDH) is very low in pancreatic β cells [5],
Figure 7.1 Glucose-induced insulin secretion (GIIS). Glucose is transported via glucose transporters and metabolized to generate ATP. Glucokinase acts as the glucose sensor. Increased cytosolic ATP closes ATP-sensitive K$^+$ (K$_{ATP}$) channels, depolarizing the plasma membrane and opening the voltage-dependent Ca^{2+} channels (VDCCs), which allows Ca^{2+} influx. The rise in intracellular Ca^{2+} concentration ([Ca^{2+}]$_i$) triggers exocytosis of the insulin granules. Glucose may generate various metabolic signals, yet to be identified, to amplify GIIS. GIIS can be modulated by hormones and neurotransmitters. VDCC, voltage-dependent Ca^{2+} channel; PKC, protein kinase C; PKA, protein kinase A; ATP, adenosine triphosphate; IP$_3$, inositol 1,4,5-triphosphate; DAG, diacylglycerol.

pyruvate readily enters the mitochondrion for subsequent oxidation.

Mitochondrial metabolism

In the mitochondrion, pyruvate is converted to acetyl-CoA by pyruvate dehydrogenase (PDH) and reacts with oxaloacetate to form citrate, an intermediate metabolite in the tricarboxylic acid (TCA) cycle. In addition, an anaplerotic pathway provides oxaloacetate for the TCA cycle directly from pyruvate by pyruvate carboxylase (PC). This reaction is also involved in the pyruvate/malate shuttle. The TCA cycle is an important metabolic circuit in terms of production of reducing equivalents in the form of NADH and FADH$_2$ for generation of ATP in the electron transport chain. Citrate is oxidized and decarboxylated to form α-ketoglutarate, which undergoes further oxidative decarboxylation to succinyl-CoA or generates glutamate by glutamate dehydrogenase (GDH). NADH is formed in these processes. Succinyl-CoA is then metabolized to succinate and converted subsequently to fumarate by succinate dehydrogenase, by which FADH$_2$ is generated. At the end of the cycle, oxaloacetate is regenerated via malate. The TCA cycle is an important aerobic pathway for the final step of the oxidation of fatty acids and certain amino acids as well as carbohydrates.

ATP generation in the respiratory chain

Activation of the TCA cycle stimulates the electron transport chain to pump H$^+$ ions out of the mitochondrial matrix, which hyperpolarizes the inner mitochondrial membrane. The respiratory chain comprises complex I (NADH-ubiquinone reductase),

II (succinate dehydrogenase), III (ubiquinol-cytochrome c reductase), and IV (cytochrome *c* oxidase). Complex I and II accept electrons from NADH and FADH2, respectively, and transport them to ubiquinone (coenzyme Q). Ubiquinone then transfers electrons to complex III, which is a multisubunit transmembrane protein encoded by both the mitochondrial and the nuclear genomes. Complex III transports electrons to cytochrome c, and then to complex IV, in which these electrons are transferred to oxygen (O$_2$), producing H$_2$O. At the same time, protons are translocated across the membrane, contributing to the proton gradient. This gradient is used by the F$_O$F$_1$ ATP synthase complex (sometimes called complex V) to make ATP via oxidative phosphorylation. Thus, in the respiratory chain, electrons move from an electron donor (NADH and FADH$_2$) to a terminal electron acceptor (O$_2$) via a series of redox reactions, which are coupled to the creation of a proton gradient across the mitochondrial inner membrane. The resulting transmembrane proton gradient is used in making ATP. Synthesized ATP is translocated to cytosol by the adenine nucleotide translocator (ANT). Since ATP production is a critical signal in the triggering pathway of GIIS from pancreatic β cells (Figure 7.1), disruption of mitochondrial function causes loss of GIIS [6,7].

NADH shuttles

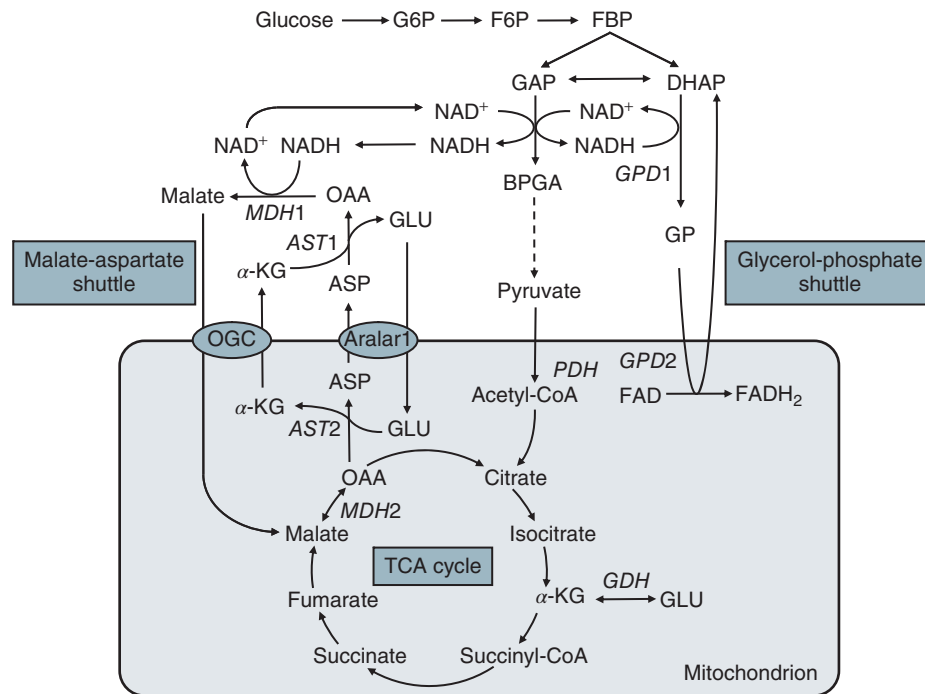
NADH shuttles are linked to glycolysis to generate NAD$^+$ in supplying electrons for the respiratory chain in the mitochondria (Figure 7.2). Pancreatic β cells cannot generate NAD$^+$ via


Figure 7.2 NADH shuttles. In the MA shuttle, cytosolic oxaloacetate (OAA) is reduced to malate using NADH+H$^+$ to generate NAD$^+$. Malate is transported into the mitochondrial matrix and then oxidized back to OAA. OAA is transformed to aspartate and moves out to the cytosol in exchange for glutamate. In the cytosol, aspartate is transaminated to restore OAA. In the GP shuttle, dihydroxyacetone phosphate (DHAP) is reduced to form glycerol 3-phosphate (GP) using NADH+H$^+$ to generate NAD$^+$. GP diffuses into the intermembrane space of the mitochondrion and is oxidized to generate DHAP, which diffuses back to cytosol, and FADH$_2$, which can be oxidized by the respiratory chain. G6P, glucose 6-phosphate; F6P, fructose 6-phosphate; FBP, fructose-1,6-bisphosphate; GAP, glyseraldehyde 3-phosphate; BPGA, 1,3-bisphosphoglycerate.

lactate formation because of extremely low LDH activity [5]. Instead, β cells possess high activity of two NADH shuttles, the malate-aspartate (MA) shuttle and the glycerol-phosphate (GP) shuttle, both of which generate NAD$^+$ via mitochondrial oxidation. In the MA shuttle, cytosolic oxaloacetate is reduced to malate by cytosolic malate dehydrogenase (MDH1) using NADH+H$^+$ to generate NAD$^+$. Malate is transported into the mitochondrial matrix in exchange for α-ketoglutarate, and then oxidized by mitochondrial malate dehydrogenase (MDH2) back to oxaloacetate, a process in which NADH is supplied for oxidative phosphorylation by the respiratory chain. Oxaloacetate is transformed to aspartate catalyzed by mitochondrial aspartate aminotransferase (AST2) and moves out to the cytosol via glutamate/aspartate carrier (Aralar1) in exchange for glutamate. In the cytosol, aspartate is transaminated by cytosolic aspartate aminotransferase (AST1) to restore oxaloacetate. In the GP shuttle, dihydroxyacetone phosphate is reduced to form glycerol 3-phosphate by cytosolic glycerol 3-phosphate dehydrogenase (GPD1) using NADH+H$^+$ to generate NAD$^+$. Glycerol 3-phosphate diffuses into the intermembrane space of the mitochondrion and is oxidized by mitochondrial glycerol 3-phosphate dehydrogenase (GPD2) to generate dihydroxyacetone phosphate, which diffuses back to the cytosol, and FADH$_2$, which can be oxidized by the respiratory chain. The

activity of GPD2 is extremely high in pancreatic islets [5,8], and decreased activity of GPD2 or the GP shuttle may be associated with type 2 diabetes [9]. However, GPD2 deficient mice do not have impaired GIIS [10,11], indicating that the GP shuttle is not essential for GIIS in pancreatic β cells. Inhibition of the MA shuttle by aminooxyacetate in GPD2 deficient mice abolishes GIIS [10]. Thus, the two NADH shuttles complementarily operate in pancreatic β cells in regulating GIIS.

Lipid metabolism
In pancreatic β cells, glucose metabolism interacts with lipid metabolism, such that GIIS is associated with inhibition of fatty acid oxidation and increased lipid synthesis. The activated form of fatty acids is long-chain acyl-CoA (LC-CoA), which is generated by acyl-CoA synthetase (ACS). The fate of fatty acids is determined by malonyl-CoA, which blocks mitochondrial oxidation of fatty acids so that LC-CoA levels are increased. A high concentration of glucose activates the TCA cycle and increases anaplerotic input of OAA, which in turn elevates export of citrate from mitochondria to cytosol via the citrate-isocitrate carrier (CIC). Citrate is cleaved by ATP-citrate lyase (ACL) to OAA and acetyl-CoA, the acetyl-CoA then being carboxylated by acetyl-CoA carboxylase-1 (ACC1) to form malonyl-CoA. Thus, glucose stimulation of β cells elevates malonyl-CoA

levels [12]. Addition of LC-CoA to permeabilized β cells stimulates insulin granule exocytosis [13], suggesting a role for LC-CoA in GIIS. Inhibition of the tricarboxylate transporter in the mitochondrial outer membrane decreases GIIS but not potassium-induced insulin secretion in rat clonal β cells [14], suggesting that export of citrate from mitochondria to cytosol is involved in metabolic signaling in the regulation of GIIS.

Metabolism-secretion coupling

Triggering pathway

Glucose metabolism increases the cytosolic ATP concentration in pancreatic β cells, this rise in ATP causing closure of the K_{ATP} channels and depolarization of the β-cell membrane. Thus, K_{ATP} channels couple the cell's metabolic state to electrical activity. The β-cell K_{ATP} channel is composed of two subunits: Kir6.2 as a pore-forming subunit and the sulfonylurea receptor SUR1 as a regulatory subunit. Activity of the K_{ATP} channel is critical for GIIS. Membrane depolarization opens VDCCs, which allows Ca^{2+} influx into β cells, the resultant rise in intracellular Ca^{2+} triggering exocytosis of insulin granules. Thus, K_{ATP} channels and VDCCs are major ion channels required for metabolism-secretion coupling in insulin release.

The intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) in pancreatic β cells is tightly regulated. Micromolar increases in $[Ca^{2+}]_i$ are required to trigger insulin secretion [15]. Opening of the VDCCs is a common step in insulin secretion induced by glucose, sulfonylureas, and amino acids [16]. The L-type VDCC generally gives rise to a transient Ca^{2+} concentration in pancreatic β cells; modulation of VDCC activity generates changes in insulin secretion [17]. Although rapid Ca^{2+} influx through VDCCs is indispensable in GIIS, increases in $[Ca^{2+}]_i$ can be slowly achieved by Ca^{2+} release from intracellular Ca^{2+} stores. It has been suggested that the mobilization of intracellular Ca^{2+} from ryanodine-sensitive Ca^{2+} stores by cyclic ADP-ribose generated by glucose stimulation contributes to GIIS [18], but the notion is controversial.

Among many Ca^{2+}-binding proteins that may function as Ca^{2+} sensors for vesicle fusion, the leading candidates are members of the synaptotagmin family [19]. Most of the 15 members share common regions and domains including a short intravesicular NH2-terminal region, a single membrane-spanning domain, a lysine- and arginine-rich region, as well as two C2 domains (C2A and C2B) located in the cytoplasmic tail [19]. Binding of Ca^{2+} to synaptotagmins via the two C2-domains transduces the Ca^{2+} signal into activation of the membrane fusion machinery, which is exerted by the interaction of the C2-domains with phospholipids and SNARE proteins [19]. Synaptotagmins 2-4 and 6-9 are expressed in pancreatic islets and β cells [20]. Synaptotagmin 7, which is co-localized with insulin granules, is thought to be the major Ca^{2+} sensor for insulin granule exocytosis [20,21].

Metabolic amplifying pathway

In addition to the K_{ATP} channel-dependent pathway that triggers insulin secretion, another pathway in GIIS augments the effect of Ca^{2+} on insulin secretion [22]. This pathway, which does not require an additional rise in $[Ca^{2+}]_i$ and is distinct from the hormonal and neuronal amplifying pathway, was originally referred to as the K_{ATP} channel-independent pathway in GIIS. However, since closure of K_{ATP} channels is a prerequisite for this augmentation pathway under physiologic conditions, it is more accurately referred to as metabolic amplifying pathway. Recent studies have focused on the mitochondrial features of this pathway. As mentioned, pyruvate readily enters the mitochondrion in pancreatic β cells and is converted to oxaloacetate by PC. In gluconeogenic tissues such as liver and kidney, the activity of PC coordinates with phosphoenolpyruvate carboxykinase (PEPCK) to initiate gluconeogenesis. Although the activity of PC is also high in pancreatic β cells, β cells lack expression of both PEPCK and fructose-1,6-bisphosphatase, indicating that PC serves in roles other than gluconeogenesis. Several lines of evidence indicate that anaplerosis via PC is involved in GIIS [23,24]. Cataplerosis pathways, which provide mitochondrial metabolites to the cytosol, are also thought to be implicated in GIIS [25]. There are at least three pyruvate cycling pathways in pancreatic β cells: the pyruvate-malate shuttle, the pyruvate-citrate shuttle, and the pyruvate-isocitrate shuttle. These pathways may generate coupling factors associated with the metabolic amplifying pathway.

Dynamics of insulin secretion

Biphasic insulin secretion

Insulin release from pancreatic β cells in response to glucose is characterized by biphasic kinetics: an initial component (1st phase), which develops rapidly but lasts only a few minutes, followed by a sustained component (2nd phase) [26–28] (Figure 7.3(a)). It has been thought that the biphasic response of insulin secretion reflects primarily the dynamics of spatially and functionally distinct insulin granules. The prevailing hypothesis is that the 1st phase of insulin secretion is attributable to fusion of predocked granules from a readily releasable pool (RRP) that accounts for less than 5% of total granules, while the 2nd phase involves recruitment of granules from a more distant reserve pool (RP) that accounts for the great majority of total granules [27–30]. A recent study using total internal reflection fluorescence microscopy (TIRFM) found three distinct modes of insulin granule exocytosis, based on dynamics of insulin granules: a mode comprising predocked granules that are immediately fused to the plasma membrane by stimulation (called *old face*), another mode comprising granules that are newly recruited by stimulation and immediately fused to the plasma membrane (a docking state can hardly be detected by TIRFM) (called *restless newcomer*), and a third mode
Figure 7.3 (a) Biphasic insulin secretion. Both 1st and 2nd phases consist of insulin granules that are recruited upon glucose stimulation and immediately fused to the plasma membrane (*restless newcomer*). RRP responsible for the 1st phase is located more than 50 nm from the plasma membrane, yet is immediately releasable. The 2nd phase of insulin secretion involves exocytosis of insulin granules from a RP. Source: Adapted from Seino 2011 [72]. Reproduced with permission of American Society for Clinical Investigation. (b) The effect of cAMP signaling in biphasic insulin secretion. Epac2A/Rap1 signaling is involved in the potentiation of the 1st phase of GIIS. Although the mechanism underlying potentiation of the 2nd phase of GIIS by cAMP signaling is still unclear, PKA may be involved. The thin line indicates the biphasic pattern of GIIS, while the bold line indicates the potentiation of GIIS by cAMP signaling. Source: Adapted from Seino 2011 [72]. Reproduced with permission of American Society for Clinical Investigation.

comprising granules that are newly recruited by stimulation, but are first paused or docked and then fused to the plasma membrane (called *resting newcomer*) [31]. In this model, a RRP responsible for the 1st phase is located away from the plasma membrane but is yet immediately releasable, and both 1st and 2nd phases of insulin granule exocytosis involve the *restless newcomer* (Figure 7.3(a)). Glucose-induced F-actin-remodeling

has recently been shown to be involved in mediating the 2nd phase of insulin secretion [32] (Figure 7.3(a)).

Exocytotic machinery

Insulin granule exocytosis in pancreatic β cells, like synaptic vesicle exocytosis in neurons, involves several processes, including granule recruitment to the plasma membrane, docking of granules at the plasma membrane, priming of fusion machinery, and fusion of granules with the plasma membrane. However, the kinetics of exocytosis is ultrafast (a few milliseconds) in synaptic vesicles of the neuron and slow (a few hundred milliseconds) in large-dose core granules of the pancreatic β cell [33,34]. SNARE proteins critical for synaptic vesicle exocytosis are expressed in pancreatic β cells and β-cell lines [34]. This exocytotic machinery, including the t-SNAREs syntaxin 1 and SNAP-25 as well as the v-SNARE synaptobrevin/VAMP-2, function similarly in insulin granule exocytosis [33,34]. Syntaxin 1 and SNAP-25 form a cluster along the plasma membrane of pancreatic β cells [35]. The rise in $[Ca^{2+}]_i$ triggers the formation of the SNARE complex from Syntaxin 1, SNAP-25, and VAMP-2, which promotes membrane fusion [19,34]. The SNARE complex is responsible for induction of insulin granule exocytosis in response to glucose [34].

In neurons, SNARE proteins interact with many vesicle-associated proteins including Sec1/Munc18 (SM) protein, Munc13, synaptotagmins, and complexin [34]. SM protein and Munc13 promote the assembly of SNARE proteins, and synaptotagmin and complexin control Ca^{2+}-dependent triggering of exocytosis [19]. SM protein associates with the closed form of syntaxins, and the closed form is presumed to prevent participation in SNARE complexes [36,37]. In pancreatic β cells Munc18-1 and Munc18c are involved in the regulation of the 1st and 2nd phases of GIIS, respectively, doing so by promoting localization of insulin granules to the plasma membrane [38]. Munc13 mediates synaptic vesicle priming by stabilizing the open conformation of Syntaxin 1, thereby allowing the formation of SNARE complexes [39,40]. In pancreatic β cells, Munc13-1 plays an essential role in the priming step in insulin granule exocytosis through its interaction with the Rab3 effector Rim2α [41]. Munc13-1 also mediates both 1st and 2nd phases of GIIS [42].

The small G-protein Rab family comprises more than 60 members [43,44]. Among them, Rab3 and Rab27a are associated with insulin granules of pancreatic β cells [45,46]. Both Rab3 and Rab27a are localized to insulin granules and function through interaction with their effector proteins Rim2α and granuphilin, respectively [41,47–49]. Rim2α plays critical roles in docking and priming steps through its interaction with Rab3 and Munc13-1, respectively [41]. The interaction of granuphilin with Syntaxin 1A/Munc18-1 is also important for docking of insulin granules to the plasma membrane [49].

Modulation of insulin secretion by various intracellular signals

GIIS is modulated by various nutrients and hormonal and neuronal inputs (Figure 7.1). Most of these hormones and neurotransmitters exert their effects on insulin secretion by binding to their specific surface receptors, which are members of the superfamily of trimeric G-protein-coupled receptors (GPCRs) [50]. Based on the properties of G-proteins, GPCRs are subdivided into different functional classes, primarily G_s, $G_{q/11}$, and G_i-protein-coupled receptors (Table 7.1). G-proteins are linked to specific signaling pathways that have multiple effects on β-cell function in the modulation of GIIS. G_s and $G_{q/11}$-proteins potentiate GIIS and may have several other beneficial effects on β-cell function [50]. G_i-protein exerts an inhibitory effect on GIIS [50]. GIIS also has been shown to be modulated by the insulin signaling pathway in rodents *in vivo* and islets isolated from rodents and humans [51–54].

As stimulation of insulin secretion is an essential pharmacologic strategy for treatment of type 2 diabetes, GPCR and the insulin signaling pathways in pancreatic β cells offer many attractive drug targets.

G_s-protein-coupled receptor

In pancreatic β cells, various hormones, neurotransmitters, nucleotides, and fatty acids including GLP-1 [55–57], glucose-dependent insulinotropic polypeptide (GIP) [55,57], vasoactive intestinal polypeptide (VIP) [58], pituitary adenylate cyclase-activating polypeptide (PACAP) [58], adrenaline, ATP/ADP, lysophosphatidylcholine (LPC) [59], and oleoylethanolamide (OEA) [60] activate their specific receptors (Table 7.1). These receptors when coupled with G_s-protein activate adenylate cyclase and increase cAMP production. These cAMP-increasing ligands potentiate both the 1st phase and 2nd phase of GIIS [61].

cAMP is mediated by protein kinase A (PKA)-independent as well as by PKA-dependent mechanisms, the former involving the cAMP-binding protein Epac2 (now called Epac2A) [47,62,63]. The effect of Epac2A on GIIS is mediated not only by its guanine nucleotide exchange (GEF) activity toward small G-protein Rap [64] but also by interactions with several other proteins, including the K_{ATP} channel regulatory subunit SUR1 [47,65,66], small G-protein Rab3 effector Rim2α [41,47,63], and Piccolo [67]. Epac2A/Rap1 signaling mediates the potentiation of the 1st phase of GIIS by cAMP [31]. It has been proposed that activation of Epac2A/Rap1 signaling increases the size of RRP and/or recruitment of insulin granules from RRP, while PKA signaling increases the size of RP and/or recruitment of insulin granules from RP (Figure 7.3(b)) [31]. Epac2A is also thought to be involved in mobilization of Ca^{2+} from intracellular Ca^{2+} stores in pancreatic β cells [68]. The effect of Epac2A is mediated by ryanodine receptors [69]. In addition, Epac2A is a direct target of antidiabetic drug sulfonylureas and is required for

Table 7.1 Ligands and GPCRs that modulate GIIS

Ligand	GPCR	G-protein	Effect on GIIS
GLP-1	GLP-1R	Gs, Gq	Stimulatory

the effect of sulfonylureas on stimulation of insulin secretion [70–72].

PKA phosphorylation of Kir6.2, VDCC α-subunits, and GLUT2 influences their activities [73–75]. PKA phosphorylation of snapin, which interacts with SNAP25 [76], increases the interaction among insulin granule-associated proteins, thereby potentiating GIIS [77]. The subcellular localization of PKA via A-kinase anchoring proteins (AKAPs) is also critical for the stimulatory effect of cAMP-elevating agents on insulin secretion [78].

The incretin hormones GLP-1 and GIP are released from enteroendocrine L cells and K cells, respectively, in response to ingestion of nutrients [55,57]. Both hormones potentiate insulin secretion in a glucose concentration-dependent manner [79,80]. The potentiating effects of GLP-1 and GIP occur at glucose concentrations higher than 5 mM *in vivo* in humans [81]. Long-term treatment with GLP-1 promotes β-cell proliferation and protects from apoptosis, thereby maintaining β-cell mass in rodent pancreatic β cells and β-cell lines [55]. GLP-1 also has an anti-apoptotic effect on primary cultured human pancreatic islets [82]. However, the proliferative capacity of human pancreatic β cells and its modulation by GLP-1 is still unclear. GIP also stimulates β-cell proliferation and has an inhibitory effect on β-cell apoptosis in rodents [55]. It has been suggested

that defects in potentiation of insulin secretion by exogenous GIP is associated with reduced expression of the GIP receptor in pancreatic β cells [83–85]. Incretin-related drugs such as dipeptidyl peptidase-4 inhibitors, which block degradation of GLP-1 and GIP, and GLP-1 receptor agonists have been developed for treatment of patients with type 2 diabetes [55].

Glucagon receptors are expressed on pancreatic β cells and glucagon stimulates insulin secretion [86,87]. The binding of glucagon to its receptor activates the G_s and G_q-proteins [87]. GIIS is enhanced in pancreatic islets that are rich in glucagon compared to that from islets containing fewer pancreatic α cells [88], which indicates that glucagon is important for the insulin secretory response to glucose. However, the contribution of glucagon receptors to β-cell function remains to be established.

GPR119, which is a receptor for fatty acid, is expressed in β cells and in pancreatic polypeptide (PP) cells [89,90]. Activation of GPR119 by lysophosphatidylcholine (LPC) [59] and oleoylethanolamide (OEA) [60] increases cAMP production and stimulates insulin secretion in a glucose-dependent manner [60,89,90].

Gq-protein-coupled receptor

G_q-protein stimulates phospholipase Cβ to produce IP_3 and DAG [50]. IP_3 triggers the release of Ca^{2+} from the endoplasmic reticulum, whereas DAG activates protein kinase C (PKC). Activation of PKC by phorbol ester, a mimic for DAG, stimulates insulin secretion in the presence of raised intracellular Ca^{2+}. It has been proposed that PKCϵ stimulates insulin secretion through the amplification of glucose metabolism [91].

Pancreatic β cells express several $G_{q/11}$-protein-coupled receptors [50] including the M3 muscarinic acetylcholine (ACh) receptor (M3R) and receptors for fatty acids (GPR40), cholecystokinin (CCKA), arginine vasopressin (V1b), and extracellular nucleotides (P2Y1 and P2Y6). The M3 muscarinic receptor is involved in the regulation of insulin secretion by the vagal nerve system. ACh has a stimulatory effect on insulin secretion in pancreatic β cells through vagal nerves, an effect that mediates the cephalic phase response to food ingestion induced by the activity of efferent vagal nerves and not by the absorbed nutrients [92]. In mouse, parasympathetic and sympathetic fibers innervate islets cells including β, α, and δ cells, while in human, islets endocrine cells are shown to be barely innervated [93]. Thus, hormone secretion in human pancreatic islets may be modulated by the autonomic nervous system via sympathetic input controlling blood flow within the islets.

GPR40 is activated by fatty acids, including docosahexaenoic acid (DHA), eicosapentaenoic acid (EPA), and arachidonic acid, and potentiates GIIS [94,95]. GPR40 has been suggested to mediate the major effect of fatty acids on insulin secretion from pancreatic β cells [94,95]. GPR40 agonists also stimulate GLP-1 and GIP secretion from enteroendocrine cells, thereby amplifying GIIS from mouse pancreatic islets [96]. A GPR40 agonist has recently been developed as a potential glucose-lowering medication by stimulating insulin secretion [97].

Gi/o-protein-coupled receptors

Somatostatin, noradrenaline, and ghrelin inhibit insulin secretion through the activation of PTX-sensitive $G_{i/o}$-protein [92,98,99], which suppresses adenylate cyclase activity. Somatostatin, which is released from pancreatic δ cells in pancreatic islets, exerts its inhibitory effect in pancreatic β cells upon binding to its specific GPCRs. There are five somatostatin receptor subtypes (SSTR1-5) [100–102]. Activation of SSTRs induces membrane repolarization and results in the reduction of action potential and Ca^{2+} influx [103,104]. SSTR2 is expressed predominantly in human pancreatic β cells [104].

$α_2$-adrenoceptors activated by noradrenaline inhibit cAMP production and open K^+ channels. Repolarization by K^+ efflux induces the closure of VDCC and the consequent inhibition of insulin secretion [92,105].

Ghrelin has an inhibitory effect on insulin secretion in rodents and humans [99,106,107]. Circulating ghrelin is produced in X/A-like cells in rat (known as P/D1 cells in human), which is distributed predominantly in the oxyntic mucosa of stomach [108,109]. Ghrelin is also expressed in pancreatic islets in humans and released into pancreatic microcirculations. Ghrelin in β cells activates growth hormone (GH) secretagogue receptor (GHS-R) that is coupled with PTX-sensitive G-protein G_{i2}, decreases cAMP production, and attenuates membrane excitability via activation of voltage-dependent K^+ channels (Kv2.1 subtype), consequently suppressing Ca^{2+} influx and insulin secretion [106,107]. It remains to be clarified how ghrelin is released from the pancreas.

Autocrine effect of insulin on insulin secretion

Rodent and human pancreatic β cells possess the various components of the insulin signaling system, including insulin receptor, insulin-like growth factor-1 (IGF-1) receptor, insulin receptor substrates (IRS-1 and IRS-2), phosphatidylinositol 3-kinase (PI3K), phosphoinositide-dependent kinase-1 (PDK1), and protein kinase B (PKB)/Akt [52,110–112]. It has been shown that insulin binds to the insulin receptors on the surface of β cells and induces phosphorylation of the insulin receptors and IRSs, modulating its own secretion [51,52,113,114]. This effect of insulin is involved especially in the 1st phase of GIIS in mice [52,113].

PI3K is a key component that transmits the insulin signal to downstream targets, and is shown to mediate regulated exocytosis in skeletal muscle and adipose tissues [115]. Three classes of mammalian PI3Ks have been identified based on their domain structures, differences in catalytic activity, and modes of regulation [116]. Class IA PI3K in mouse pancreatic β cells contributes to normal regulation of GIIS through the maintenance of expression levels of SNARE proteins and the control of intracellular Ca^{2+} levels [54,117,118]. Class II PI3K-C2α is also activated by insulin in mouse insulinoma cells and promotes GIIS via PKBα/Akt1, an isoform of PKB/Akt [119]. Knockdown of PI3K-C2α impairs insulin granule exocytosis in rat insulinoma cells [120]. The expression level of PI3K-C2α mRNA in islets of type 2 diabetic patients is decreased compared to that

Pathophysiology of pancreatic β cells

β-Cell mass and function in type 2 diabetes

Type 2 diabetes is characterized by impaired insulin secretion and/or insulin resistance. However, insulin secretory capacity is the major determinant in the development of type 2 diabetes, as neither hyperglycemia nor glucose intolerance develops in insulin-resistant patients as long as sufficient insulin is secreted from β cells in a timely fashion in response to various stimuli. Impaired insulin secretion may be due to β-cell dysfunction, reduced β-cell mass, or both. Loss of β-cell mass in type 2 diabetes patients has been reported [121]. However, surgical and chemical reductions of β-cell volume induce functional adaptation of the normal β cell to prevent a rise in fasting glucose or reduction in the 1st phase of insulin secretion [122,123], suggesting that β-cell dysfunction is closely associated with the pathogenesis and pathophysiology of type 2 diabetes.

Abnormalities in the dynamics of insulin secretion

Abnormal dynamics of insulin secretion selective for glucose stimulation, especially the acute phase of the insulin response, is already reduced in the early stage of type 2 diabetes, patients with IGT, and their first-degree relatives [124,125]. As the early phase of insulin secretion is determined by the RRP, a reduction in its size and/or impairment of signaling for exocytosis of the insulin granules from the RRP may well develop in IGT and the early stage of type 2 diabetes. The RRP is completely depleted and the RP is markedly reduced in the fully developed stage of type 2 diabetes. Signaling mechanisms underlying exocytosis of insulin granules from the RRP and the RP may also be defective in type 2 diabetes.

Although the pulsatile nature of insulin secretion is maintained in patients with type 2 diabetes, with a number of pulses similar to that in healthy control subjects, the pulses after meals are less frequent, irregular, and have a significantly lower amplitude, resulting in a marked disruption of the dynamics of post-meal insulin secretion [126]. A loss of coordinated insulin secretory responses to oscillatory glucose infusion is found in subjects with IGT, indicating a defect in the ability of the β cells to properly sense and respond to parallel changes in the plasma glucose level [127]. Thus, abnormalities in the dynamics of insulin secretion may be an early manifestation of β-cell dysfunction preceding the development of overt type 2 diabetes.

Conclusions

Mechanisms of insulin secretion in pancreatic β cells have been extensively studied for decades, and many intracellular signals that trigger or amplify insulin secretion have been identified. Glucose metabolism is essential for both the triggering and amplifying pathways of insulin secretion. Besides glucose, lipid metabolism in β cells is also implicated in insulin secretion. Many molecules associated with the exocytotic machinery of insulin granules have been identified recently. Advances in technologies of imaging and mass spectrometry enable us to visualize insulin granule dynamics in living β cells and to analyze cellular proteins and metabolites in a comprehensive manner. Clarification of the molecular and cellular mechanisms of insulin secretion should provide a basis for identifying novel therapeutic targets as well as deeper understating of the pathogenesis and pathophysiology of diabetes.

Key points

- Insulin is crucial for survival in an environment where feeding is discontinuous and requires fine regulation of metabolism.

- Sophisticated methods have been developed over the past decades to study the multifaceted aspects of *in vivo* β-cell insulin secretion.

- The normal β cell responds to intravenous glucose challenge with a complex multiphasic secretory pattern, encompassing short and transient insulin release (first phase), sustained response (second phase) and potentiation of insulin secretion for longer term glucose exposure.

- The β-cell response to intravenous glucose is potentiated when glucose is ingested orally (incretin effect); two intestinal hormones, GIP and GLP-1, mediate this phenomenon.

- Insulin secretion is further stimulated by the ingestion of proteins, as amino acids are secretagogues; fat and protein ingestion stimulate incretin hormones that potentiate insulin secretion.

- Many other factors including other gastrointestinal hormones, neuropeptides, and the nervous system are likely to contribute to controlling and modulating insulin secretion.

- Insulin resistance enhances insulin secretion, particularly in fasting conditions.

- The β-cell mass is rather variable between normal subjects; while β-cell mass is expected to impact on function, the relationship between mass and function appears to be weak.

- Peripheral insulin levels are controlled by β-cell secretion, hepatic insulin removal, and whole-body insulin clearance.

- The complex and integrated response of the β cell is fundamental to maintain glucose levels within a relatively narrow range, despite very different environmental and metabolic conditions.

Introduction

Insulin is an ancient hormone; it emerged early in evolution since the most primitive forms of vertebrates (extant lamprey and hagfish) evolving from insulin-like peptide genes, which are expressed in all multicellular animals [1]. From an evolutionary point of view insulin facilitates survival in an environment where access to nutrients is discontinuous, erratic, and difficult, requiring the function of highly specialized tissues necessary to allow movement and appropriate reactions to external stimuli (i.e., skeletal muscle and nervous system). Insulin, in the fed state is secreted to stimulate glucose and amino acids uptake allowing the build-up of depots of glycogen, proteins and lipids, which are necessary to sustain the energy requirements during successive fasting.

It is therefore not surprising that insulin secretion is dynamic and strictly controlled by plasma glucose concentration in a feedback system that maintains rather stable plasma glucose concentrations despite erratic feeding (i.e., glucose homeostasis). The homeostatic control system is, however, asymmetric, as insulin is the only hormone counteracting hyperglycemia, while hypoglycemia is prevented by at least three other hormones (cortisol, glucagon, and adrenaline). Insulin secretion, in contrast with most of the other hormones, is also only marginally regulated by the central nervous system; the intestine through the gut hormones, reliable sensors of the feeding state, is probably the most important "distant" site of control for insulin secretion.

Insulin's effect on the different target organs (Figure 8.1) depends on the interstitial concentrations of the hormone, which in turn depend on its secretion rate and the rate of its removal from the circulation (insulin clearance). Insulin is secreted into the portal vein and in the fasting state the portal hormone levels restrain liver supply of glucose into the systemic circulation to exactly match the need of glucose-dependent tissues (central and peripheral nervous system and red blood cells). The low levels of insulin attained in the systemic circulation in the fasting state, due also to an elevated first pass insulin clearance by the liver, allow the release of free fatty acids (FFA) from adipose tissue depots (lipolysis) so as to privilege lipids

Fasting

Fed
Figure 8.1 Glucose homeostasis in the fasting and in the fed state. The type of relationship between the process (*y* axis) and insulin concentration (*x* axis) is depicted in skeletal muscle (*y* = glucose uptake) and adipose tissue (*y* = NEFA release); the pancreas takes exception since the process (insulin secretion) is on the x axis. In the fasting condition insulin (dark gray) is controlled by plasma glucose (gray) and controls glucose production by the liver and limits the release of NEFA (light gray) from adipose tissue. The glucose produced by the liver is used mostly by the brain, whose glucose uptake is not dependent on insulin. In the fed state glucose enters into the circulation from the portal entry, signals from the gut amplify β-cell glucose sensitivity, insulin is secreted in large amount and glucose is taken up by the liver, which also stops its production, and by peripheral tissue, mostly muscle. The high insulin levels inhibit the release of NEFA by adipose tissue while stimulates glucose uptake also in this tissue.

utilization over glucose for energetic needs. The size and the energetic density of lipid stores are in fact much greater than those of carbohydrates.

In the fed state insulin is secreted in proportion to the increments in plasma glucose levels caused by glucose entrance into the circulation from food absorption and digestion. The increased portal insulin and glucose concentrations reduce liver glucose production and promote liver glucose uptake allowing the refill of the organ glycogen depots. Systemic insulin concentration increases, because of reduced liver insulin clearance in comparison to the fasting state, resulting in an efficient inhibition of lipolysis and fatty acid release, stimulation of glucose utilization in insulin-dependent tissues (mainly adipocyte, and skeletal muscle), and replenishment of body glycogen and lipid stores. Because of these concerted effects plasma glucose increases during feeding remain limited (max $2-3$ mmol L^{-1}) and return to premeal levels within $2-3$ hours after the ingestion of food.

This chapter provides an account of the basic methods and main concepts concerning the physiology of *in vivo* insulin secretion in humans, including a brief mention of the role of insulin clearance. For each topic we will provide, when available, quantitative information and discuss its relevance to overall glucose homeostasis.

Methods for the assessment of insulin secretion

The functional characteristics of the β cells are evaluated *in vivo* using a variety of experimental approaches and measurements,

which have been conceived to investigate the complex response of the β cell. These methods are described here mainly for their value in understanding the physiology of insulin secretion in response to intravenous and oral glucose; a more detailed description of the tests can be found in dedicated reviews [2,3].

Relationship between plasma insulin concentration and insulin secretion

The measurement of insulin concentration has been considered the most obvious approach to evaluate insulin secretion and it is still the reference method in the perfused pancreas or islet cultures. In contrast, *in vivo* measurement of plasma insulin concentration is believed to provide a potentially biased assessment of insulin secretion because a large fraction of the secreted insulin is removed by the liver before it reaches the systemic circulation [4]. Furthermore, insulin clearance, which is a main determinant of plasma insulin concentration, is not constant, neither in an individual nor across subjects with different characteristics (e.g. lean vs. obese, see the dedicated paragraph in this chapter). The current methodology for *in vivo* assessment of insulin secretion is based on the measurement of plasma C-peptide, which is co-secreted with insulin in equimolar amounts as a consequence of pro-insulin cleavage. C-peptide is virtually not extracted by the liver, and has a clearance that is considered to be more constant than that of insulin [5,6]. Insulin secretion (usually expressed in pmol min^{-1} or pmol min^{-1} per square meter of estimated body surface area) is calculated from C-peptide concentration using a mathematical operation called "deconvolution" [7]. The most common deconvolution approach

relies on standardized parameters of C-peptide kinetics, calculated from the individual anthropometric characteristics [6].

Caution should be used in the comparison across studies of insulin and C-peptide concentrations and the derived indices, as the assays are not standardized and significant differences exist between the measurement methods. An additional potential source of inhomogeneity is the conversion factor used to express the common units of insulin ($\mu U\,mL^{-1}$) in SI units ($pmol\,L^{-1}$); while the correct conversion factor should be 6 ($1\,\mu U\,mL^{-1} = 6\,pmol\,L^{-1}$) [8], in many instances other factors have been used.

Insulin secretion indices
Absolute insulin secretion in itself may not be an adequate index of β-cell function, unless a standardized stimulus is provided, as insulin secretion is glucose-dependent and glucose levels vary widely under physiologic circumstances. For this reason, a common rationale of several tests is to use experimental protocols in which glucose levels are standardized, such as in the hyperglycemic clamp (described later). Under standardized conditions, appropriate indices of insulin secretion can be directly calculated. In contrast, the analysis of tests of physiologic interest such as the oral glucose tolerance test (OGTT), in which glucose levels cannot be controlled, is more problematic. Several empirical indices have been proposed largely based on the ratios between insulin concentration (or secretion) and glucose concentration [2,3]. Mathematical models have also been used, as described in the following section.

Mathematical models
The use of mathematical models for the interpretation of the β-cell response is as old as the initial extensive studies on β-cell function [9–11]. Modeling, indeed, allows a better quantitative evaluation of the mechanisms underlying insulin response to a challenge and allows the estimation of β-cell function also from tests in which glucose levels are not standardized.

Models have been used in the analysis of intravenous glucose tolerance test (IVGTT) [12–14] and the OGTT [15–20]. The modeling methods for the assessment of β-cell function in essence embed a mathematical description, of variable but limited complexity, of the relationship between glucose concentration and insulin secretion (or concentration). The model equations contain parameters representative of β-cell function that are estimated by fitting the mathematical model to the measured data (glucose and insulin or C-peptide concentration). There are common aspects in these models, such as the presence of a dose-response relating insulin secretion to glucose concentration, but also differences, particularly in the interpretation of the OGTT.

The models for the IVGTT are rather approximate, as in these conditions it is difficult to accurately represent the insulin response with simplified approaches. Thus, the validation of this method has been limited, in particular for the parameters quantifying late insulin response.

The OGTT models have been used in a variety of conditions, thanks to the relative experimental simplicity of the test. Two main model strains have been employed, which differ in the representation of late insulin secretion during the test. The first, largely derived from the IVGTT models, assumes that insulin secretion is delayed with respect to the glucose concentration by a first-order delay [16,18]. This delay can describe the sustained insulin secretion response often observed at the end of the test. The second approach assumes that the sustained response is due to potentiation of insulin secretion [19,20]. The latter approach appears to have more experimental support, as potentiation phenomena have been clearly demonstrated *in vivo* in man.

β-Cell response to intravenous glucose

Although in normal living conditions β cells are stimulated by hyperglycemia that follows glucose ingestion, the study of the response to intravenous glucose is of fundamental importance for understanding the physiology of β cells. Several tests have been developed for this purpose and this section describes the most relevant and the characteristics of insulin secretion that they reveal.

The hyperglycemic clamp
The most typical test for the study of β-cell response employs a brisk and sustained elevation of glucose concentration from a baseline value. In vivo, this is typically achieved with the hyperglycemic clamp technique (Figure 8.2) [21]. The β-cell response to this glucose stimulus is biphasic, with an initial insulin secretion burst lasting about 5–8 min (first-phase secretion), followed by a drop towards basal levels and then by a relatively rapid increase that persists as far as hyperglycemia is maintained (second-phase secretion).

One important physiologic feature highlighted by the hyperglycemic clamp is that the β cell responds to the increase in glucose in a proportionate manner. In other words, β-cell function, as for many other physiologic processes, can be described through a dose-response curve describing the relationship between insulin secretion and glucose concentration in steady-state conditions (Figure 8.2). This dose-response can be assessed with greater accuracy using a stepped increase in glucose concentration, the so-called graded glucose infusion test [22]. In this test, glucose is infused intravenously at increasing rates and glucose and C-peptide are measured. Insulin secretion is calculated by deconvolution of C-peptide and the β-cell dose-response is constructed by plotting insulin secretion rates at the end of each glucose infusion period versus the corresponding glucose concentration.

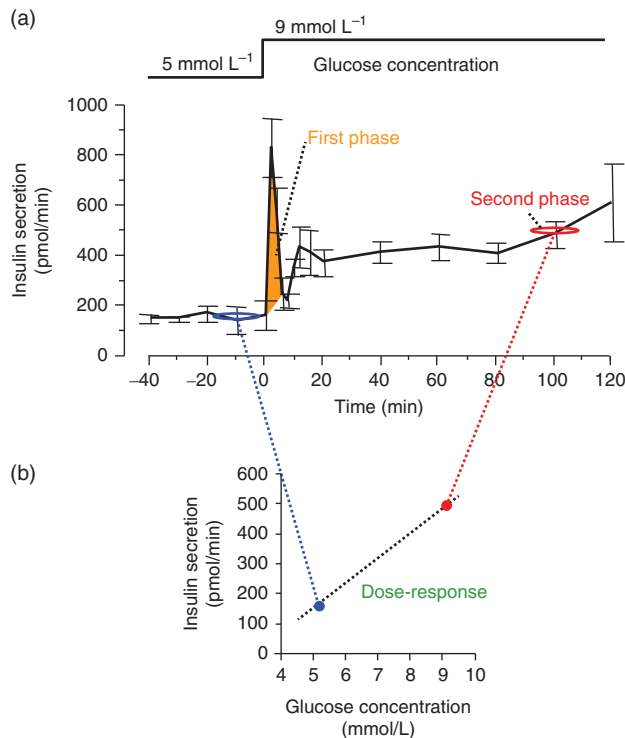
The β-cell dose-response is a fundamental characteristic of insulin secretion; its slope, which represents the sensitivity of the β cell to glucose, is a key β-cell function parameter. In healthy subjects insulin secretion at a basal glucose level of $5\,mmol\,L^{-1}$ is about 90 pmol min^{-1} and increases by five- to


Figure 8.2 Hyperglycemic clamp. In the hyperglycemic clamp, glucose concentration is briskly elevated from the basal level using a suitable intravenous glucose infusion (a). The sharp glucose increase elicits a rapid and short-lived insulin secretion peak (first-phase secretion), followed by a drop towards basal levels and then by a relatively rapid return to a sustained value in the second half of the clamp (second-phase secretion). The hyperglycemic clamp assesses insulin secretion at two steady-state glucose levels (fasting and elevated glucose); a rudimentary β-cell dose-response can be determined from these data (b).

sixfold (500 pmol min^{-1}) at 10 mmol L^{-1} [22]. The relationship is fairly linear within this glucose concentration range and above; under these circumstances, β-cell glucose sensitivity (i.e., the dose-response slope) is about 80 pmol min^{-1} per mmol L^{-1}.

First-phase secretion becomes evident with a brisk elevation of glucose concentration. The amount of insulin secreted during the first phase is dependent on the magnitude of the glucose increase, so that even the first phase recognizes a dose-response feature [9]; in a typical +7 mmol L^{-1} hyperglycemic clamp it is around 4 nmol m^{-2} representing the 10–15% of what is secreted per hour in the second phase [23]. Though limited, the amount of insulin secreted in the first phase is relevant at least for two reasons. First, while the secretion burst is apparent with a rapid elevation in glucose concentration, the underlying secretory mechanisms appear to be active even for a more gradual rise in glucose concentration [9]. These mechanisms are likely to be responsible for a response that is anticipated compared to what would be predicted solely on the basis of the dose-response and this anticipation has relevant physiologic implications for glucose homeostasis, as discussed later. Second, first-phase insulin secretion is a very sensitive marker of early β-cell dysfunction

[24]. Impairment of first-phase secretion is already present in subjects at risk of developing diabetes [25], and is predictive of diabetes onset [26]. Because of these relevant characteristics, assessment of first-phase secretion has been widely used.

The intravenous glucose tolerance test

A common technique for the assessment of first-phase insulin secretion is the intravenous glucose tolerance test (IVGTT, also known as FSIGTT, frequently sampled intravenous glucose tolerance test), in which glucose (typically 0.3 g kg^{-1}) is injected intravenously over a short period of time (2–3 min). The sharp rise in glucose concentration elicits a first-phase response similar to that observed in the initial part of the hyperglycemic clamp, which is commonly quantified using the so-called acute insulin response (AIR) [27]. This widely used index is typically calculated as the mean increment above baseline in insulin concentration in the first 8–10 min. An advantage of the IVGTT is its relative experimental simplicity, compared to the clamp. Moreover, similarly to the hyperglycemic clamp, parameters of insulin sensitivity can be derived as well [28]. Many of the studies concerning the relationships between insulin sensitivity and insulin secretion, discussed later, are based on this approach [29]. In contrast to AIR, late-phase insulin secretion is not commonly calculated during IVGTT testing.

When evaluated using C-peptide deconvolution, the amount of insulin secreted during the IVGTT first phase is estimated to be ~3 nmol m^{-2}, a value similar to that of the hyperglycemic clamp [30,31].

In summary, insulin secretion when assessed with intravenous glucose challenges appears to be highly dynamic with two main characteristic phases, a rapid and transient one followed by a more sustained one. These responses can be reproduced *in vitro*, by pancreas perfusion as well as in perifused islets [9,32]. Nonetheless, the mechanisms underlying the biphasic response remain only partially understood. It has been proposed that first-phase secretion is the consequence of the discharge of a pool of insulin granules located in the proximity of the cell membrane in response to an increase in intracellular calcium triggered by a cascade of electrochemical events generated by glucose utilization inside the β cell [33]. Exocytosis, however, is very sensitive to calcium levels and the typical early peaking of intracellular calcium [34] may well exert a direct contribution to this phenomenon. Second-phase secretion is also controlled by calcium, but glucose itself, independently from calcium, plays a role in sustained insulin secretion [35].

β-Cell response to oral glucose

The amount of insulin secreted above the basal levels during a 2-h 75 g OGTT in normal subjects is ~30 nmol m^{-2} [31]. The insulin response to glucose ingestion is more pronounced than that elicited by an intravenous infusion achieving the same glucose levels. This difference becomes readily apparent when the

plasma glucose profile after an OGTT is reproduced by means of an intravenous infusion of glucose [36,37]. The greater response to oral glucose is referred to as the "incretin effect."

The incretin effect

As shown in Figure 8.3, when glucose concentration changes during the OGTT, insulin secretion follows the glucose pattern, although insulin secretion is considerably higher after oral ingestion. This implies that the β-cell dose-response for oral glucose is shifted upwards compared to that for intravenous glucose (Figure 8.3). Estimates of the magnitude of the potentiating effect of oral glucose in normal subjects vary from study to study, partly because of the different methods used to calculate the incretin effect. Recent studies based on modeling analysis report an increase in insulin secretion of ~1.6–1.7-fold with oral (75 g OGTT) compared to intravenous

glucose administration [38,39]. The incretin effect appears to be quite variable also within subjects with normal glucose tolerance, ranging from a negligible effect to a two- to threefold amplification. The incretin effect is dose-dependent, that is, higher glucose doses elicit stronger effects; for a fivefold increase in the glucose load, the increase in incretin effect is almost twofold, from ~1.2 to ~2.4 [38,40].

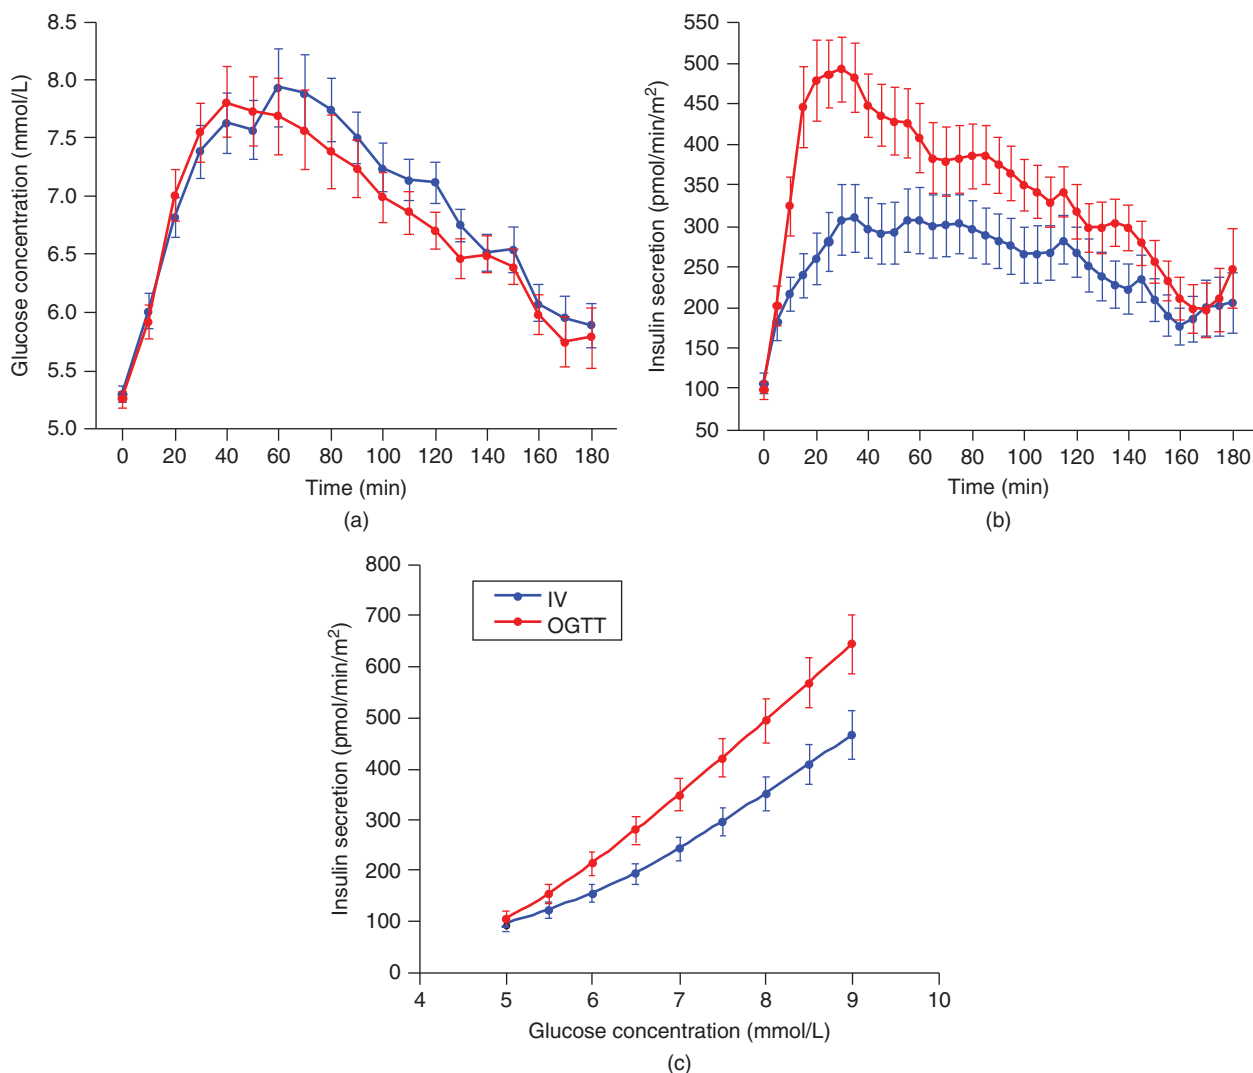
The incretin effect is mainly attributed to the action of two hormones: glucose-dependent insulinotropic peptide (GIP) and glucagon-like peptide 1 (GLP-1) [41]. GIP and GLP-1 are secreted as glucose and other nutrients reach sections of the intestine where cells specialized in the secretion of these hormones are located (the K cells for GIP and the L cells for GLP-1) [42,43]. GIP and GLP-1 bind to specific receptors on the β cell that activate a cascade of events leading to increased insulin secretion. The action of these hormones is glucose-dependent,


Figure 8.3 Incretin effect. In the test for the assessment of the incretin effect, the glucose profile observed during an OGTT (a; lighter line) is reproduced by means of a controlled intravenous glucose infusion (a; darker line). At similar glucose levels, insulin secretion is considerably increased during oral glucose ingestion (b). Consequently, the β-cell dose-response relating insulin secretion to glucose concentration is shifted upwards (c). Source: Data from [39].

that is, the increase in insulin secretion is higher when glucose concentration is higher, whereas at low glucose the amplification is marginal. GIP and GLP-1 may also act indirectly on the β cell through stimulation of the nervous systems, as receptors for these hormones are present in neuronal cells [44]. The secretion of GIP and GLP-1 is dependent on the amount of nutrients reaching the intestine.

Experiments employing exogenous infusion of GIP and GLP-1 have clearly shown that these hormones stimulate insulin secretion in a concentration-dependent fashion [45,46]. In particular, GLP-1 has been shown to make the β cell dose-response steeper [45], similarly to Figure 8.3. However, whether GIP and GLP-1 levels can entirely account for the incretin effect has not been fully established. The relationship between the levels of incretin hormones and the incretin effect are in fact generally weak [38,47,48]; whether this is due to limited assay precision or factors other than the hormone levels remains to be clarified.

Insulin secretion mechanisms during an oral glucose load

OGTT modeling analysis has enabled more careful assessment of the multiple components of insulin secretion (Figure 8.4) [19]. According to this approach, the β cell dose-response is responsible for most of the changes in insulin secretion during an OGTT. Early secretion mechanisms, which enhance insulin secretion during the initial part of the OGTT, contribute only one tenth ($\sim$3 nmol m^{-2}) of total supra basal secretion ($\sim$30 nmol m^{-2}) (unpublished results from [31]). Notably, the magnitude of the early insulin secretion component is similar to that calculated during the hyperglycemic clamp or an IVGTT. Therefore, based on this analysis the contribution of early secretion phenomena is quantitatively limited during an oral glucose load as well.

The response to oral glucose is also characterized by phenomena that enhance β-cell glucose sensitivity during the test, referred to as "potentiation." This mechanism may well account for persistent activation of insulin secretion at the end of the OGTT when glucose concentration has returned to baseline levels [20,31]. Modeling analysis predicts that in normal subjects at the end of a 2-h OGTT insulin secretion is $\sim$70% higher compared to baseline at the same glucose levels [31].

As described earlier (Figure 8.3), a key effect of the stimulation of the incretin system is the upward shift of the β-cell dose-response, that is, an increase in glucose sensitivity. In addition, the incretin effect also enhances early secretion [38,39]. The influence of the incretin effect on potentiation is more complex. A recent study [48] has shown that the potentiation phenomena observed during an OGTT are a combination of the incretin effect and glucose-induced potentiation, a mechanism described later in this chapter.

Insulin secretion in normal living conditions

During a 24-h observation period in which meals are administered at the usual times, insulin secretion excursions basically
Figure 8.4 Insulin secretion components during an oral glucose load. As glucose concentration increases and successively decreases during a normal 2-hour OGTT (top), insulin secretion follows a similar pattern (bottom, black line). The β-cell dose-response explains most of the insulin secretion excursions (bottom, gray line). However, in the initial period insulin secretion is relatively higher (bottom, horizontally banded area); this anticipative response accounts for 10–15% of the total suprabasal secretion. During the last part of the OGTT, glucose concentration returns to baseline (horizontal dashed lines), while insulin secretion does not. This relative enhancement of insulin secretion is denoted as potentiation (bottom, vertically banded area); at the same glucose levels, insulin secretion at the end of the OGTT is about 70% greater than at baseline. Insulin secretion components are obtained by modeling analysis [19,20].

follow glucose excursions during the multiple meals [49], similar to a single OGTT. However, some studies have reported that the β-cell dose-response does not remain the same during the 24 hours. In particular, in relation to the glucose levels insulin secretion is relatively potentiated during the morning meal and attenuated during the following meals and the night, to a significant extent [20,50].

β-Cell response to nonglucose secretagogues

Proteins and amino acids

The insulinotropic effect of oral proteins was first described almost 50 years ago [51–53] and recently confirmed [54–56]. After the ingestion of a small amount of proteins (30–50 g) [51,55] or a larger amount of proteins (2 g kg^{-1}) [56], plasma insulin was raised two- to threefold over baseline and remained persistently elevated for 90 or 240 minutes, respectively. In either case, blood glucose did not change, whereas both GLP-1 and GIP levels were raised threefold over fasting values [55,56].

Because the effect of the incretins is glucose-dependent [41], the insulinotropic effect of oral proteins was most likely elicited by a direct stimulation of β cells by amino acids. In support of this hypothesis, it has been shown that insulin response to different protein solutions was closely related to the increase of plasma amino acids [57–59] with large differences among the individual amino acids unexplained by the functional group [60]: phenylalanine and glycine shown to be the most potent ($+30$ pmol L^{-1}), histidine, tyrosine, and, surprisingly, arginine as neutral, and the others as intermediate ($+10.5$ pmol L^{-1}).

In vitro studies [61] have reported that the insulinotropic effect of amino acids is mostly dependent on the amino acid type, duration of exposure and concentration; furthermore only combination of amino acids stimulates insulin secretion when added at physiologic concentrations, whereas higher concentrations of individual amino acids are required to activate insulin secretion [61]. Accordingly, the intravenous administration of a relatively small number of amino acids individually promotes insulin release while the maximum stimulus is elicited by mixed amino acids [62]. In contrast to other amino acids, homocysteine *in vitro* showed a dose-dependent negative effect on insulin secretion in pancreatic β cells [63].

When either amino acids or proteins were ingested with glucose, plasma insulin levels were not significant or only slightly different from those after oral glucose alone but at lower glucose concentration [52–55,59,60,64,65] suggesting a direct effect on β-cell glucose sensitivity. Interestingly, the insulinotropic effect of proteins was neither blunted by insulin resistance [66] nor by diabetes [67] and was largely explained by the enhanced GLP-1 and GIP responses.

Lipids and free fatty acids

The first evidence of the insulinotropic effect of nonesterified fatty acids (NEFA) dates back five decades [68–70]. Several subsequent studies, described later, led to heterogeneous results which may be explained by differences in study protocols, dose (pharmacologic/physiologic), chemical structure (level of saturation, length of the carbon chain), type of administration (acute/chronic, oral/intravenous) and in subjects' individual features (body weight, fasting glycemia, family history of diabetes) [61,71].

In lean subjects, an acute elevation of NEFA has a minor effect upon basal insulin concentration, but significantly increased glucose-stimulated insulin secretion [72–75]; this effect is blunted in obese subjects [73,74], and it is not confirmed when NEFA are infused for 10 h [76] or ingested simultaneously with glucose [66,77]. The acute enhancement of glucose-stimulated insulin secretion seems to be dependent on the type of NEFA ingested, being more relevant after monounsaturated than after polyunsaturated and saturated NEFA [75].

Studies investigating the chronic effects of NEFA elevation yielded more conflicting results. A 24–48-h lipid infusion

has been reported to reduce [78], increase [79] or not significantly change [80] glucose-induced insulin secretion. A 72-h increase in plasma NEFA concentration produced an enhanced insulin response to the hyperglycemic clamp, but no effect on basal insulin concentration and, interestingly, the effect was opposite in the subjects with family history of type 2 diabetes (T2DM) [81]. In overweight and obese subjects 24-h repeated ingestion [82] of polysaturated NEFA resulted in a greater increase of plasma insulin levels than in mono- and fully saturated, although the analysis of C-peptide profiles revealed a reduction in insulin clearance. The evidence that NEFA may affect insulin clearance has also been reported in healthy lean subjects [80,83,84] and represents another confounding factor when investigating the insulinotropic effects of NEFA.

Animal [85–87] and *in vitro* [70,88–90] studies show that an acute elevation of NEFA increases both basal and glucose-stimulated insulin secretion while reducing insulin clearance, whereas chronic elevation of NEFA may increase basal insulin secretion but inhibits the secretion stimulated by glucose. Different effects were elicited by different NEFA, depending on their chain length and degree of saturation [91,92].

Slow β-cell response modes and adaptation mechanisms

The secretion mechanisms discussed above are relatively rapid and typically suited to coping with the insulin needs of a meal. The healthy β cell can also respond with slower modes, adapting to insulin demand if required by the metabolic conditions.

Glucose-induced potentiation of insulin secretion

Slow response modes are unveiled by prolonged exposure to hyperglycemia or repeated glycemic stimuli. During a hyperglycemic clamp, particularly at high glucose levels (>10 mmol L^{-1}), the second-phase response exhibits a slow progressive rise over time [23]. When two consecutive hyperglycemic episodes are brought about, the insulin response after the second one is higher compared to the first [11]. With a prolonged (three day) infusion of glucose at a low constant rate, the insulin response assessed with a hyperglycemic clamp before and after the infusion is increased more than twofold [93]. Similarly, a prolonged glucose infusion makes the β-cell dose-response, assessed with the graded glucose infusion test, steeper [22]. When glucose is infused intravenously to mimic the response to an oral glucose test, increasing glucose doses and concentrations produces an upward shift of the β-cell dose-response, that is, insulin secretion becomes greater for the same glucose level [38]. The common denominator of these phenomena is that sustained hyperglycemia potentiates insulin secretion; this mechanism provides an additional resource to control glucose levels.

Another classical experiment showing the potentiating effect of exposure to hyperglycemia involves the use of arginine as a secretagogue. An arginine bolus elicits a burst of insulin secretion similar to that of the IVGTT. When the arginine bolus is administered in a hyperglycemic state created by a hyperglycemic clamp, the insulin secretion response is potentiated compared to the basal state [94]. In normal subjects, the magnitude of this potentiation increases almost in proportion to the glucose levels until it reaches a plateau above ∼30 mmol L^{-1} glucose, where the response to arginine is more than fivefold the response at basal glucose. The initial slope of this curve, denoted as the glucose potentiation slope, is an index of the ability of glucose to potentiate insulin secretion [94].

Adaptation to insulin sensitivity

A widely studied adaptive mechanism of the β cell is the modulation of its response by prevalent insulin sensitivity. It is a longstanding observation that obesity is accompanied by insulin resistance and hypersecretion [95]; the widespread use of the IVGTT for the simultaneous assessment of insulin sensitivity and secretion has consolidated the notion that insulin secretion, and in particular fasting insulin secretion and the first-phase response (AIR), is inversely related to insulin sensitivity [27,29,96]. Thus, insulin-resistant subjects with normal glucose tolerance secrete more insulin to cope with the increased insulin demand.

Based on observations largely derived from the IVGTT, it has been proposed that the relationship between insulin secretion and insulin sensitivity is hyperbolic [27]. According to this paradigm, a more appropriate index of β-cell function is the product of the insulin secretion and sensitivity indices, as on the hyperbola representing normal compensation this index is constant. The product of the insulin secretion and sensitivity indices has been historically denoted as the "disposition index" [28]. The disposition index, rather than the absolute insulin secretion response, should reflect intrinsic β-cell function.

Although the experimental evidence supporting the disposition index concept has been mostly derived for AIR and the IVGTT assessment of insulin sensitivity, the paradigm has been often assumed to apply to other indices of insulin secretion. This has been criticized because it has been shown that the assumption of a hyperbolic relationship is not valid for all indices [97,98]. In the presence of inverse relationships of other kinds, the disposition index provides a biased assessment of β-cell function [98].

Physiologically more important is that β-cell glucose sensitivity obtained from an OGTT is not related to insulin sensitivity [31,99]. Therefore, while insulin resistance does upregulate fasting insulin secretion and the first-phase response, the most important β-cell function index of the OGTT is not affected. This implies that compensation for insulin resistance is of particular importance for the tuning of fasting insulin secretion

and therefore fasting glucose, while the secretion mechanisms that regulate postprandial glucose are less influenced by this form of adaptation.

β-Cell response to hormones and the nervous system

As already mentioned insulin is the only hormone with a blood glucose lowering effect, while many other hormones (glucagon, cortisol, adrenaline) exert a hyperglycemic action. The changes in glucose levels elicited by these hormones obviously will be detected by the β cell, which will respond by enhancing insulin secretion. Yet, all these hormones, as well as others and the nervous system exert a coordinated direct effect on the β cell resulting in an integrated and sophisticated control network. The typical example is the intra-islet networking encompassing the entangled interaction between α, β, and δ cells [100]. Glucagon released from the α cell has a stimulatory effect on insulin secretion by the β cell, an effect that is commonly used to test residual endogenous insulin secretion *in vivo* [101]. The latter requires, however, pharmacologic doses of glucagon (1 mg), while the small increase in circulating insulin levels observed with glucagon infusion is more likely the result of the hyperglycemic effect of the hormone. Insulin secretion, in turn, exerts an inhibitory effect on glucagon secretion, whereas somatostatin, released from δ cells, suppresses secretion of both insulin and glucagon [102], and therefore, is believed to integrate pancreatic islet hormonal effect. More recently an interaction between somatostatin and ghrelin has been reported in regulating insulin release [103]. On top of the direct effect on the β cell, resulting in suppression of both basal and stimulated insulin secretion, somatostatin may exert an effect on insulin secretion also through modulation of a number of gastrointestinal hormones, for instance by inhibiting, with different potency, the release of gastrointestinal hormones [104].

The effects of GLP-1 and GIP on insulin secretion have already been mentioned but other gastrointestinal hormones may contribute to modulating insulin secretion. For instance, animal studies have indicated that ghrelin can counteract the insulinotropic effect of GLP-1 [105]. An even greater inhibitory effect has been claimed to be exerted by obestatin [106] though variable and divergent effects may be elicited by different levels of the hormone [107]. Leptin, secreted by the adipocyte, interacts with receptors located on the β cell where it causes reduced insulin gene expression and inhibits insulin secretion by a KATP channel dependent and independent pathway [108].

Contra-insular hormones such as catecholamines [109], cortisol [110], and growth hormone via the effects of IGF-1 [111] mainly exert a suppressive effect on insulin secretion, which may not be readily appreciated because of the concomitant induction of insulin resistance.

More complex appears to be the role of the nervous system. Claude Bernard first suggested the involvement of the nervous system in the regulation of insulin secretion. His hypothesis was then supported by the discovery by Langerhans that pancreatic islets were indeed highly innervated. Subsequently it was found that parasympathetic, sympathetic, and sensory nerve endings are present that can affect insulin and the β-cell function through the release of a number of neurotransmitters [112]. These include catecholamine and acetylcholine as well as neurotransmitters such as the vasoactive intestinal polypeptide (VIP), pituitary adenylcyclase activating polypeptide (PACAP), the gastrin-releasing polypeptide (GRP), galanin, neuropeptide Y, and the calcitonin gene-related polypeptide (CGRP). The response of the β cell to nerve stimulation is the result of the balance between the stimulatory effects of the parasympathetic nerve endings and the inhibitory one of the sympathetic nerves. However, much of the information is derived from animal studies, whereas investigation into the innervation of the human islet is limited [113–115]. Acetylcholine and noradrenaline are locally released to act on cholinergic and adrenergic receptors. Acetylcholine stimulates insulin by enhancing Ca^{2+} release from intracellular depots, while activation of α_2-adrenergic receptors suppresses glucose-mediated insulin release [116] via hyperpolarization of the β-cell membrane thus contributing to rapid adaptation of insulin secretion under conditions of hypoglycemia. On the contrary a stimulation of insulin secretion is elicited by activation of β_2-adrenergic receptors. A potential role in the neuronal regulation of the activity of pancreatic islet cells appears to be exerted also by sensory fibers, including fibers containing neuropeptides GGRP and substance P, since pancreatic sensory denervation has been proposed to contribute to defective insulin secretion in Zucker diabetic animals [117].

To make the picture even more complex is the observation that a number of neurotransmitters (i.e., galanin, melatonin, melacortin, orexin, vasopressin, and so on) may also contribute to modulate β-cell function [118]. Also in this case, however, much of the information has been obtained with *in vitro* studies using murine islet models, while a careful profile of the human islet is still far from available. Moreover, the evaluation of the physiologic role of innervation of the pancreatic human islet poses a number of interpretation issues as stimulation or inhibition of the parasympathetic and sympathetic branches of the autonomic nervous system elicits an array of responses (metabolic changes, regional blood flow, release of multiple neurotransmitters and neuropeptides) that can ultimately result in a direct effect on the β cell. By using more selective pharmacologic agents such as tyramine, a negative effect of sympathetic activation on insulin secretion induced by *i.v.* arginine has been confirmed in human subjects [119].

The islet innervation may play a main role in humans by mediating the cephalic phase of insulin secretion, that is, the rapid increase in insulin secretion occurring in the first couple of minutes upon initiation of the stimulus [120]. Thus, pharmacologic denervation (parasympathetic and sympathetic inhibition by trimetaphan) results in the abolition of the cephalic phase of insulin secretion, without affecting early GLP-1 and GIP secretion [121].

More recent observations suggest that the autonomic nerves may also play a role in the synchronization of the islet ensuring simultaneous and harmonic response of the islets as a unit [122].

Pulsatile secretion of insulin

Insulin secretion is a very dynamic process. This characteristic is even more appreciated if the typical pulsatile secretion of the hormone is taken into consideration. Insulin oscillates with a slow ultradian periodicity (∼140 min) and a high frequency periodicity [123]. Pulse intervals have been recently calculated in a more reliable manner and shown to occur with a periodicity of 4–6 min in humans [124]. These oscillations suggest the pancreatic islet has a pacemaker function. This efficient pulsatile secretion requires formidable coordination of the secretory activity of the β cell dispersed through the 1 million pancreatic islets scattered in the 25-cm long human pancreas. This coordination process is believed to require the integrated action of intra-islet nerves, metabolites, and hormones [125]. Recent studies have shown that oscillation of intracellular calcium is synchronized with β-cell metabolism [126]. Many factors affecting insulin secretion also impact on pulsatility of insulin secretion. Both sulfonylureas and GLP-1 can enhance *in vivo* pulsatility [127]. Although oscillatory insulin secretion may have a role in modulating insulin action, particularly at the level of the liver, it has also been proposed recently that this pattern may have a major effect at the level of the β cell by preventing desensitization of the insulin signaling pathway that contributes to regulation of β-cell mass [128]. Pulsatility, indeed, leads to periods of low autocrine stimulation enabling the cell to set with the background concentration of circulating insulin and other growth factors. The pulse release is believed to improve release control and enhance the action of the hormone. Studies performed in normal as well as diabetic individuals have shown that less insulin is required to maintain euglycemia with pulsatile versus continuous insulin administration [129].

β-Cell mass and function

β-Cell mass can be accurately evaluated only through autopsy studies [130,131]. Complex *in vivo* tests aiming at measuring maximal secretory capacity combining different stimuli have been proposed [94,132] as an alternative. However, their ability to discriminate between defects in function and mass, as well as their feasibility, is a matter of debate [133]. As thoroughly reviewed by Robertson [134], the acute response to

an *i.v.* glucose bolus in normoglycemic subjects and the acute response to an *i.v.* arginine bolus in hyperglycemic subjects do correlate with β-cell mass. However, the severity of the defects observed with these tests in T2DM [94] contrasts with the relatively preserved mass size observed at autopsy suggesting that *in vivo* investigations cannot distinguish between defects of mass and function. More recently, external detection of β-cell mass through metabolic tracers has been attempted but, up to now, the reliability of these methods remains limited [135].

Autopsy studies have consistently demonstrated that the whole body β-cell mass in a normal adult man is approximately 0.9 g and displays a wide inter-individual variability (95% CI: 0.5–1.3 g). Assuming 1 ng per cell and a fasting insulin production of 75 pmol min^{-1} m^{-2} this means that glucose homeostasis in man relies upon "only" 900,000,000 cells, each producing approximately 90,000 molecules per minute and five-to sixfold more in the stimulated condition [33].

Obesity is a marginal factor in determining total β-cell mass as it accounts for a 0.2 g increase for any 10 units of BMI. The dimension of this cell pool expands slowly and gradually from 0.2 to 20 years of age [136] remaining relatively stable thereafter being only marginally influenced by aging [130,131]. In rodents pregnancy is associated with β-cell proliferation until mid gestation to drop to the nonpregnant stage after parturition [137].

The reasons for the large individual variability in β-cell mass in adults ranging from 500 to 1500 million cells is not fully understood but a genetic influence cannot be ruled out as suggested by the observation that several type 2 diabetes susceptibility genes are involved in β-cell development (*PDX1*, *PTF1A*, or *HNF1B*) and apoptosis (*INS*, *HNF4A*, *EIF2AK3*, *WFS1*, or *FOXP3*) [138].

The workload imposed on each single cell will vary in inverse proportion to the initial asset and, as a corollary, the β-cell functional reserve must be wide enough to guarantee normal glucose homeostasis in most individuals. As evident from autopsy [130,131] and pancreatic surgery [139] studies, this functional reserve is approximately twofold, with hyperglycemia usually ensuing for reduction of >50% of the original β-cell mass. After hemi-pancreatectomy similar glucose values are achieved in response to either oral or *i.v.* glucose in spite of 50% lower insulin response suggesting that the reduction of β-cell mass translates into—or mimics—a diffuse and severe β-cell dysfunction. The small impact on glucose tolerance is likely to depend on the simultaneous reduction of glucagon [140] and/or increase in insulin sensitivity. Interestingly, in a similar experimental setting the C-peptide:glucose ratio was found to correlate with the residual β-cell mass [141]. However, the explained variance was less than 50% and it was present only when the subjects with diabetes, those with impaired and those with normal glucose tolerance were evaluated altogether. These observations suggest that a reduction in β-cell mass can translate into impaired function. However, such an effect tends to become evident only in extreme conditions (i.e., existing insulin resistance), whereas, in a more physiologic setting, the

relationship between mass and function is not present or is rather loose.

The evidence of heterogeneous, and sometimes selective, β-cell dysfunctions in subjects with mild impairments in glucose homeostasis [25], points to a minor impact of β-cell mass on physiologic glucose homeostasis. This is also supported by the demonstration that mild-to-severe degrees of β-cell dysfunctions can be reversed by intensive blood glucose-lowering therapy [142] or bariatric surgery [143]. In an elegant study performed in nondiabetic subjects undergoing partial pancreatectomy [144] the same ~50% reduction of the β-cell mass, resulted in different degrees of β-cell dysfunction depending on the subject's insulin sensitivity, underscoring the discrepancy between mass and function. Finally, in a very recent study in a rodent model of T2DM [145] a significant fraction (75%) of β cells were found to be present but not producing insulin in response to glucose, confirming the dissociation between function and mass.

Insulin clearance

Insulin clearance is usually expressed in two ways, depending on the site of entry of the hormone into the circulation: (i) exogenous (or peripheral) insulin clearance, which can be determined experimentally through a euglycemic glucose clamp as the ratio between exogenous insulin infusion and arterial insulin concentration at steady-state, and (ii) endogenous (or prehepatic) insulin clearance, which is calculated as the ratio between endogenous insulin secretion and arterial insulin concentration at steady-state. The latter is an important determinant of plasma insulin concentration in physiologic conditions; however, its direct experimental determination is hampered by the difficulty in gaining access to the portal vein where endogenous insulin is secreted. Thus, its determination typically rests on the indirect calculation of insulin secretion through C-peptide deconvolution. Assembling data from different studies and our own data, in Figure 8.5 we provide estimates of the values of whole body and major organs insulin clearance in a subject both in the fasting state and during a 2-h OGTT; the two conditions will be discussed separately.

Insulin clearance in fasting conditions

In quantitative terms the fraction of portal insulin that is removed by the liver in its first pass is approximately 65%, ranging between 50 and 70% [50,146–148]. Once into the systemic circulation, insulin is cleared again by the liver with a similar efficiency and to a lesser extent by the skeletal muscles and the kidneys. The overall contribution of the liver (first pass plus recirculation) is therefore dominant (approximately 90%).

Information on the biologic variability of endogenous fasting insulin clearance is lacking and can be indirectly inferred from the data on exogenous insulin clearance. Exogenous insulin

Figure 8.5 Insulin clearance rates and insulin fluxes in a normal man (70 kg, body surface area 1.73 m²) in the fasting condition (upper panel) and in the fed state (lower panel). Below each tissue (liver, kidney, and skeletal muscle) the rate of insulin clearance, expressed in L min⁻¹, is shown. The values expressed in "U day-1" or in "U per 2h" units represent the amount of insulin that is released by the pancreas (prehepatic) and the insulin that reaches the peripheral circulation (post hepatic). In the gray boxes, the amount of insulin, in units, that is cleared by the near tissue is indicated. The numbers in the light gray arrows indicate the insulin concentration into the portal vein and in the post-hepatic veins.

clearance displays a large inter-individual variability, which is chiefly (∼50%) explained by genetic factors [149,150] and, to a lesser extent (∼20%), by the negative effect of abdominal obesity and liver fat [151], and insulin resistance [152]. The role of insulin clearance in the maintenance of glucose homeostasis is commonly interpreted as compensatory, with lower values being observed in those who are more insulin-resistant and would take advantage of increased insulin levels. This may not hold true since experimental animals in which insulin clearance was reduced by knocking out the insulin degrading enzyme [153], after a transient mild improvement in glucose metabolism developed insulin resistance and diabetes. Similarly, fasting hyperinsulinemia and mild degrees of insulin resistance developed in pancreas-transplanted patients with organ venous drainage into the systemic circulation compared to those with portal drainage [154]. In physiologic conditions there is no convincing evidence that endogenous insulin clearance plays a role in the control of fasting glucose homeostasis [155].

Insulin clearance in the fed state
In the fed state endogenous insulin clearance is lower compared to fasting (Figure 8.5) as a consequence of the saturation of hepatic insulin removal for elevated insulin concentrations and possibly of other unknown factors. The contribution of the muscle is reduced [156] while that of the kidney is increased [147] although together they still contribute no more than 20% to overall insulin clearance. The 25–30% reduction with respect to the fasting rate displays a wide inter-individual variability (from

10 to 40%), which is largely, though not entirely, explained by the different insulin concentrations (lower clearance for higher levels). A recent study [157] has revealed the mechanism for the saturation and a source of variability: mice lacking the transporter (ZnT8), which enriches the insulin vesicles in zinc, demonstrate that this ion is responsible for the inhibition of the clathrin-dependent insulin endocytosis in the liver and subjects with a single nucleotide polymorphism in the gene encoding for this transporter also display an increased insulin clearance during an OGTT. Little information is available on the nongenetic factors that influence the reduction in insulin clearance observed in the fed state. A role of the central nervous system is possible [158] as well as signals other than GLP-1 from the gut [159] to the liver via nitric oxide generation [23,160].

The presence of reduced insulin clearance in all the conditions of hyperinsulinemia/insulin resistance (diabetes, obesity, fatty liver) has led to the conclusion that the changes in clearance are compensatory: they guarantee higher peripheral levels at similar secretion rates. This association, however, is largely dependent on the saturation phenomenon and it is thus very difficult to extrapolate the contribution of insulin clearance to glucose homeostasis independently of the prevailing plasma insulin levels. On the other hand, there is evidence that insulin clearance can influence glucose tolerance independently of other factors. For instance, an acute 30% increase in insulin clearance, produced by systemic nitric oxide inhibition, is able to deteriorate glucose tolerance in normal subjects [23]. Furthermore, surgical alteration of insulin clearance in pancreas-transplanted patients with portal or systemic pancreatic drainage [154] produces homeostatic changes that are independent of β-cell function. Therefore, in the fed state insulin clearance, by modulating insulin levels, appears to contribute to glucose homeostasis in concert with, and not in response to, insulin sensitivity and secretion.

β-Cell function and glucose homeostasis

Insulin secretion, together with the sensitivity to insulin of glucose-utilizing tissues, is a key player in glucose homeostasis. What is relevant for glucose homeostasis is not the absolute insulin secretion levels but insulin secretion relative to glucose, as typically assessed by the β-cell dose-response during the physiologic condition of oral glucose ingestion (Figure 8.3). Thus, β-cell glucose sensitivity is strongly inversely associated to mean glucose levels during a standard OGTT and explains, together with insulin sensitivity, a substantial proportion of the variability in glucose levels [31,99].

It should be recalled that two distinct mechanisms determine glucose sensitivity: the ability of the β cell to respond to intravenous glucose and the incretin effect. Both these mechanisms contribute to glucose homeostasis in a significant manner [38,161].

The different modes of response of the β cell exert a specific role in the regulation of glucose levels. One important aspect is the control of fasting glucose levels, which is achieved by a modulation of fasting insulin secretion. In healthy subjects, insulin resistance does not produce relative fasting hyperglycemia, as the fasting secretory tone is properly upregulated, to the extent that fasting glucose is not related to insulin sensitivity [31]. Notably, upregulation of fasting secretion occurs through an upward shift of the β-cell dose-response, induced by insulin resistance. This mechanism is specific for the basal condition, as it does not affect the dose-response slope, that is, glucose sensitivity [31].

The role of the early secretion mechanisms is more difficult to ascertain. The ability of the normal β cell to anticipate the secretory response is reputed to provide a "priming" mechanism that compensates for the relatively slow action of insulin in muscle, or possibly restrains glucose production more efficiently [162]. Indeed, the estimate of early secretion obtained by modeling analysis has been shown to be related to glucose levels [31]. A more direct proof of the relevance of an anticipated secretory response comes from a study evaluating the effects on glucose levels of two insulin profiles with the same mean value but different timing: the anticipated profile produces lower glucose than the delayed one [163].

Potentiation phenomena also have a role in glucose tolerance. Enhancement of insulin secretion at the end of an OGTT compared to the beginning has been shown to be related to 2-h glucose [31,164]. It is also likely that the potentiation phenomena observed during the 24 hours contribute to a more efficient control of glucose tolerance.

Conclusions

The β cell is an extraordinary organ. Only one gram of tissue exerts a function that is fundamental for living. The β-cell response exhibits a high degree of sophistication and can finely tune insulin secretion to cope with the metabolic needs. Appropriate control of glucose levels, indispensable for healthy living, is almost entirely ensured by this small but powerful organ. β-Cell dysfunction may therefore easily result in alterations to the multiple biologic action of the hormone. As discussed in depth in Chapter 24, β-cell dysfunction is a key feature of diabetes. Comprehension of the mechanisms controlling such a fine and articulated function is not straightforward, but gaining an understanding of the as yet unresolved questions in order to pave the way for new and more effective cures for this widespread disease is of prime importance.

Neuropeptides and islet hormone secretion

Bo Ahrén

Department of Clinical Sciences Lund, Lund University, Lund, Sweden

Key points

- Autonomic nerves, being parasympathetic, sympathetic or sensory, innervate the pancreatic islets.

- When these nerves are activated they release neurotransmitters, which diffuse a short distance to the islet β and α cells and activate specific receptors resulting in stimulation or inhibition of islet hormone secretion.

- Islet nerves also innervate islet blood vessels, and may therefore also affect islet function through changes in blood flow.

- Besides the main neurotransmitters, acetylcholine in parasympathetic nerves and noradrenaline in sympathetic nerves, the islet autonomic nerves also release neuropeptides.

- The main islet nerve neuropeptides are pituitary adenylate cyclase-activating polypeptide (PACAP), vasoactive intestinal polypeptide (VIP) and gastrin-releasing polypeptide (GRP) in parasympathetic nerves, galanin and neuropeptide Y (NPY) in sympathetic nerves and calcitonin gene-related peptide (CGRP) and substance P in sensory nerves.

- The parasympathetic nerves, through their neurotransmitters stimulate insulin and glucagon secretion, whereas the sympathetic nerves, through their neurotransmitters inhibit insulin secretion and stimulate glucagon secretion.

- The physiologic function of the autonomic nerves is still not established, although they may be of importance for the islet hormone response to the early phase of feeding and stimulation of glucagon secretion during hypoglycemia.

- Several key questions need to be solved in future research for a thorough understanding of islet neurobiology, the impact of the islet autonomic nerves for physiology and pathophysiology, and the relative contribution to such impact by the neuropeptides.

Introduction

The traditional view is that islet hormone secretion is mainly regulated by circulating nutrients (glucose, amino acids, free fatty acids) as well as the gut incretin hormones (glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP)). However, in certain circumstances regulation of insulin and glucagon secretion is also dependent on the autonomic nerves which innervate the islets [1]. These nerves belong to the parasympathetic, sympathetic, and sensory branches of the autonomic nervous system (Figure 9.1(a)). Their nerve terminals traverse in close apposition to the islet endocrine cells and contain in their vesicles both the classical neurotransmitters (acetylcholine and noradrenaline) and several neuropeptides, which are released from activated nerves (Figure 9.1(b)). The neurotransmitters then diffuse a short distance to the islet β- and α cells and activate specific receptors resulting in stimulation or inhibition of islet hormone secretion (Figure 9.1(c) illustrates the parasympathetic-islet complex). The islet nerves also innervate the islet blood vessels, and may therefore also affect islet function through changes in blood flow.

Islet parasympathetic nerves

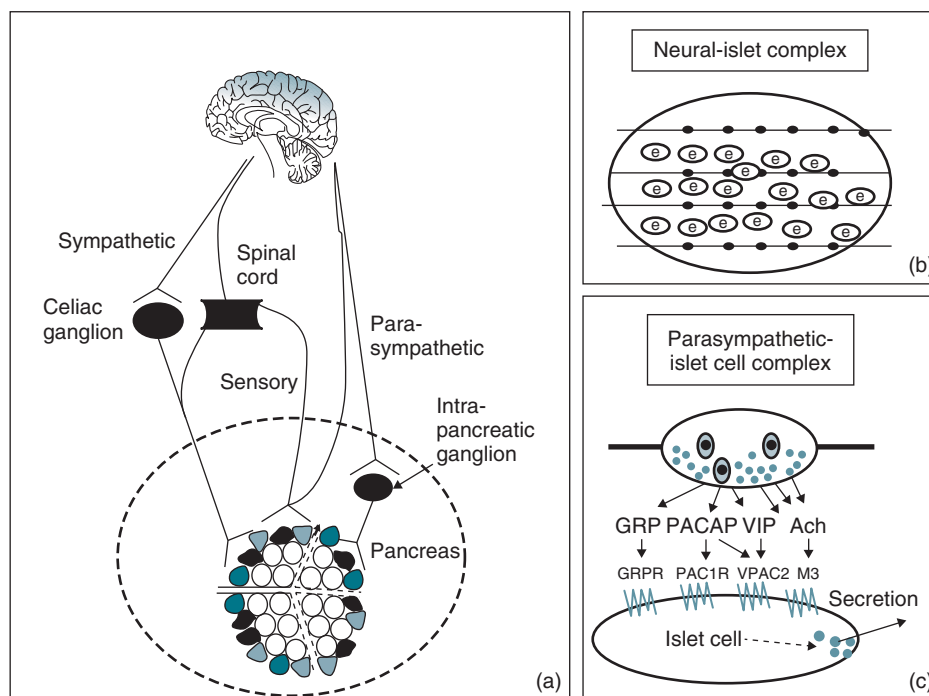
The parasympathetic nerves innervating the islets originate in the pancreatic ganglia, whose activity is controlled by preganglionic nerves, originating in the dorsal motor nucleus of the brain [1]. In addition, the adjacent duodenum projects parasympathetic fibers to the pancreatic ganglia [2]. The preganglionic nerve fibers form classical nerve terminals and synapses within the ganglia where they release acetylcholine to activate nicotinic receptors on the postganglionic neurons. The nerves have small vesicles which contain acetylcholine and large dense core vesicles which contain neuropeptides. Both acetylcholine and neuropeptides are released from small varicosities in the nerves, from which they diffuse to the islet endocrine cells and activate specific receptors which cause stimulation of both insulin and glucagon secretion. A main physiologic importance of this regulation is the early phase


Figure 9.1 (a) Schematic view of the innervation of the pancreatic islets by the main branches of the peripheral nervous system. (b) Schematic view of an islet with the varicosities (dots) of autonomic nerves and islet endocrine cells "e". (c) Schematic view of a single varicosity (top) of an islet parasympathetic nerve containing small vesicles which release acetylcholine and large dense core vesicles which release neuropeptides (GRP, VIP, and PACAP) onto their receptors to stimulate secretion from an islet endocrine cell (bottom).

of feeding, both during the cephalic phase of meal-induced insulin secretion, which is the release in anticipation of the meal, and during the first few minutes after food is ingested but before significant amounts of nutrients have reached the islets to stimulate insulin secretion directly [3]. Another physiologic importance of the parasympathetic islet nerves may be, together with the sympathetic nerves, the stimulation of glucagon secretion during hypoglycemia [4].

The classical mechanism invoked to explain stimulation of insulin and glucagon secretion during vagal nerve activation is the release of the neurotransmitter acetylcholine. The released acetylcholine diffuses to the endocrine cells and activates muscarinic receptors (mainly the M1 and M3 subtypes of the muscarinic receptor) which results in stimulation of insulin and glucagon secretion [5]. The intracellular second messenger system induced by muscarinic receptor activation involves phospholipase C (PLC) with increased formation of inositol-1,4,5-trisphosphate (IP_3) and liberation of calcium from intracellular stores; this occurs in conjunction with formation of diacyl glycerol (DAG) and subsequent activation of protein kinase C (PKC) [6,7]. Another mechanism is phosphorylation-/arrestin-dependent coupling of the muscarinic M3 receptor to protein kinase D1 [8].

The critical importance of the cholinergic mediation of islet hormone secretion for glucose homeostasis is evident from studies using mice with either β-cell deletion of the M3 receptors or β-cell overexpression of M3 receptors [8]. The

β-cell M3 knockout mice have defective insulin secretion and glucose intolerance, whereas β-cell M3 receptor overexpressing mice have increased insulin secretion and enhanced glucose tolerance. The mice with β-cell overexpression of M3 receptors are also resistant to diet-induced glucose intolerance and hyperglycemia [8].

Neuropeptides contained in islet parasympathetic nerve terminals may also contribute to vagally induced stimulation of insulin and glucagon secretion, since in the dog insulin secretion after vagal nerve activation is not abolished by atropine, which blocks the muscarinic receptors. However, it is abolished by hexamethonium, which blocks the nicotinic receptors needed to activate postganglionic nerves [9]. The neuropeptides localized to islet parasympathetic nerve terminals and therefore potential mediators of the islet noncholinergic effects are gastrin-releasing polypeptide, vasoactive intestinal polypeptide, and pituitary adenylate cyclase-activating polypeptide [9].

Gastrin-releasing polypeptide (GRP)

GRP is the mammalian homologue of the amphibian peptide bombesin. It consists of a 27-amino acid residue, which is α-amidated in its C-terminal methionine. The peptide is highly conserved during evolution, having an identical N-terminal end to bombesin, and the human and porcine forms of the peptide differ in only two residues. GRP is widely distributed

in mammalian tissues, with particular abundance in the lung, the central nervous system, and the gut. In the pancreas, GRP is localized to islet nerves [1] and nerve terminals in the pancreatic ganglia, and is released from the isolated pig pancreas during vagal nerve activation [10]. GRP stimulates insulin secretion as shown in experimental studies in mice, pigs, and dogs [10–12]. This stimulation is mediated by activation of both β-cell and ganglionic GRP receptors, as evident from findings *in vivo* that the ganglionic antagonist hexamethonium and the muscarinic antagonist atropine both partially inhibit GRP-stimulated insulin secretion [1,13]. A main mechanism underlying the direct β-cell stimulation of GRP is increased cytoplasmic calcium due to stimulation of both calcium uptake from extracellular space and release from intracellular stores [14]. However, PKC [15] and phospholipase D (PLD) may also contribute to GRP-induced insulin secretion [1]. Hence, activation of several different signaling mechanisms may together contribute to the insulinotropic action of GRP.

Bombesin-like peptides activate several subspecies of receptors, but it is the GRP receptor (GRPR) that is the receptor subtype responsible for GRP-stimulated insulin secretion [16]. To study the physiology of GRP and islet function, mice with genetic deletion of the GRPR have been developed. These mice exhibit impaired insulin secretion in response to autonomic nerve activation by neuroglycopenia induced by 2-deoxyglucose (2-DG) [16]. 2-DG is known to activate the autonomic nerves, thereby increasing insulin secretion in mice by an effect that is counteracted by ganglionic blockade by hexamethonium [1]. Insulin secretion in response to oral glucose is also impaired in GRPR-deleted mice, indicating involvement of GRP in neural stimulation of insulin secretion after meal ingestion [17].

In contrast to the well-documented stimulation of insulin secretion by GRP, its potential effect on glucagon secretion is not established. One study demonstrated stimulation of glucagon secretion by GRP in mice [11], but other studies in dogs showed no effect on glucagon secretion [12]. Overall, GRP's role seems more related to the insulinotropic than the glucagonotropic action of the parasympathetic nerves.

Vasoactive intestinal polypeptide (VIP)

VIP was originally isolated from the porcine small intestine in the early 1970s and found to consist of 28 amino acid residues, with a C-terminal α-amidation showing structural similarities to other members of the glucagon superfamily of peptides [18]. VIP is formed by processing of 149-amino acid proVIP and is highly conserved as illustrated by human, porcine, and rat VIP being identical and differing from guinea pig VIP by only two amino acids.

VIP nerves are localized both to the central nervous system and to the respiratory, gastrointestinal, and genitourinary systems. This neuropeptide exerts a variety of actions, including relaxation of smooth muscle cells and stimulation of exocrine

and endocrine secretions. In the pancreas, a neural VIP network surrounding the islets has been demonstrated both in humans and experimental animals and it has also been demonstrated that islet VIP nerves show particular association with the centrally located insulin-producing cells [19,20]. VIP has also been demonstrated in ganglionic nerve cell bodies, the source of the parasympathetic nerves that innervate the islets. Like GRP, VIP is also released from the pancreas when the vagal nerves are activated [20]. VIP is a powerful stimulator of insulin secretion as demonstrated after exogenous administration *in vivo* and *in vitro* [21]. Similarly, transgenic mice overexpressing the VIP gene in the islet β cells show increased insulin secretion and increased glucose tolerance with a reduction of circulating glucose [22].

Two VIP binding receptors exist and because they also show affinity for pituitary adenylate cyclase-activating polypeptide (PACAP) they are called the VPAC1 and VPAC2 receptors (VPAC1R and VPAC2R) [23]. They are both G-protein-coupled receptors having seven transmembrane domains. *In situ* hybridization using probes for the messages of VPAC1R and VPAC2R has demonstrated that VPAC2R but not VPAC1R is expressed in rat and mouse islets as well as in insulin-producing clonal cells [24]. This suggests that it is VPAC2R that transmits the VIP signal to islet endocrine cells. Through activation of VPAC2R, VIP activates adenylate cyclase, which increases the formation of cyclic AMP (cAMP), as has been demonstrated in islet cells [25]. cAMP in turn activates PKA, which enhances exocytosis in both direct and indirect manners. VIP also stimulates glucagon secretion as demonstrated in several species [21]; however, the mechanism underlying the glucagonotropic action of VIP has not been established.

Pituitary adenylate cyclase-activating polypeptide (PACAP)

PACAP exists in two forms, 27 and 38 amino acids, both of which, like VIP, belong to the glucagon superfamily. VIP and PACAP show 68% identity. The C-terminal 11 amino acids of PACAP38 are cleaved to produce PACAP27, with the main form being PACAP38 [26]. PACAP is found mainly in nerves of the central nervous system, the lungs, and the gastrointestinal tract. It is also found in nerve terminals and their neuronal cell bodies in pancreatic ganglia, as demonstrated both in mice and rats [26]. The localization of PACAP to autonomic nerve terminals in humans has not yet been established. The islet PACAP nerves are thought to be mainly parasympathetic nerves, because PACAP is co-stored with VIP in some islet nerves, is released from the pancreas during electrical activation of the vagal nerves, and pancreatic PACAP content is reduced by vagotomy.

PACAP potently stimulates insulin secretion as demonstrated both *in vivo* and *in vitro* [21,26]. It also augments glucose-stimulated insulin secretion in healthy volunteers

upon exogenous administration, showing that PACAP is an insulinotropic neuropeptide in humans [27]. PACAP stimulates insulin secretion in a glucose-dependent manner via activation of adenylate cyclase, increased formation of cAMP, and activation of PKA [26]. PACAP also increases the cytoplasmic concentration of calcium and sodium through opening of membranous calcium and sodium channels, and stimulates a distal effect on the exocytosis machinery. The potency of PACAP to stimulate insulin secretion, which exceeds that of VIP, is likely due to the diversity of intracellular signals it activates to stimulate islet β cells.

There is a close relation between PACAP and VIP, which is evident by the structural similarity of the peptides and by the affinity of both peptides for VPAC1R and VPAC2R. However, PACAP also stimulates a third subtype of receptors, which is specific for PACAP. This receptor, the PAC1 receptor (PAC1R), like the two VPAC receptors, is G-protein-coupled and has seven transmembrane domains [23]. Gene expression and *in situ* hybridization studies have shown that PAC1 receptors and VPAC2 receptors are expressed in islets [26]. To study the physiology of PACAP, PAC1R knockout mice have been made [28]. These mice are viable, develop normally and have normal baseline glucose and insulin levels as well as normal pancreatic insulin content. The insulin response to PACAP is reduced by 50% in PAC1R knockout mice, showing that a main mediator of the PACAP-induced insulin secretion is the PAC1 receptor. A most interesting phenotype in the PAC1R-deleted mice is that they exhibit an impaired insulin response to glucose, both *in vivo* and *in vitro*. This suggests that PAC1R contributes both to PACAP- and glucose-induced insulin secretion, that is, PACAP is of physiologic importance for glucose-stimulated insulin secretion. In regard to these PAC1R-deleted mice, it is important to remember that expression of VPAC1R and VPAC2R is still intact, which likely allows PACAP to still exert some stimulation of insulin release and may explain why PACAP-induced insulin secretion is not abolished, but reduced only by approximately 50% in the PAC1R-deficient mice. Therefore, studies on VPAC1R- and VPAC2R-deleted mice are important for a more complete understanding of the insulinotropic role of PACAP. PACAP knockout mice are unlikely to be useful in this regard since they exhibit high mortality and have a marked psychomotor phenotype although their islet function has not been studied [26].

Because of its localization to parasympathetic nerves in the pancreas and release from the pancreas after vagal nerve activation as well as its potent stimulation of insulin secretion, PACAP may be of physiologic relevance for neural regulation of islet function before and during meals. Results showing that the insulin response to oral glucose in mice is inhibited by a PACAP receptor antagonist and impaired in PAC1R-deleted mice support this hypothesis [26,28]. However, further studies are needed to determine its exact role.

PACAP has also been shown to stimulate glucagon secretion in several species, including humans [21,26,27]. It therefore mimics both the stimulation of insulin and glucagon secretion induced by parasympathetic nerve activation. The glucagon response to insulin-induced hypoglycemia has also been shown to be impaired in mice with genetic deletion of PAC1 receptors [29], which may suggest that PACAP contributes to neurally induced glucagon counterregulation.

Parasympathetic effects and mediation

As reviewed earlier, activation of the parasympathetic nerves stimulates both insulin and glucagon secretion, and this may be of particular relevance for the cephalic and early meal phases of insulin secretion as well as for the glucagon response to hypoglycemia. These effects may be mediated by the classical neurotransmitter acetylcholine and by the neuropeptides confined to these nerves (GRP, VIP, and PACAP). These four neurotransmitters are all potent stimulators of insulin and also, with the exception of GRP, glucagon secretion, and therefore mimic effects of parasympathetic activation on islet hormone secretion. In classical neurobiology, several criteria need to be met before a candidate neurotransmitter, such as these neuropeptides, can be proven to be a physiologic neurotransmitter [30] (Table 9.1). These criteria include that the potential neurotransmitter is localized to the nerves, is released by activation of the nerves, its effects mimic that of the nerves and that inhibition of its effect alters the responses to nerve activation. Some of these criteria have been met for GRP, VIP, and PACAP, and therefore some of them are strong candidates for physiologic neurotransmitters (see Table 9.2). Currently, convincing evidence has been presented for VIP and PACAP and evidence also exists for GRP. However, further studies are still required to firmly establish the involvement of GRP, VIP, and PACAP in parasympathetic control of islet function.

Islet sympathetic nerves

Islets are densely innervated by sympathetic nerves, as demonstrated by fluorescence microscopy, electron microscopy, and immunocytochemistry [1]. The islet sympathetic nerves are

Table 9.1 Four criteria for a proposed function of neurotransmitter in the islets [30]

Criterion 1	The potential neurotransmitter mimics the effects of nerve activation on insulin or glucagon secretion when exogenously added to islets (direct stimulation)
Criterion 2	The neurotransmitter is localized to islet nerve cells
Criterion 3	The neurotransmitter is released from the pancreas when the nerves are activated
Criterion 4	Interference with effect of the potential neurotransmitter (receptor antagonist or genetic deletion of neurotransmitter or receptor) alters response to nerve activation

Table 9.2 Application of the criteria from Table 9.1 for neurotransmitters in the parasympathetic islet nerves to mediate the stimulation of insulin and glucagon secretion which is achieved by activation of the parasympathetic nerves

	Criterion 1		Criterion 2	Criterion 3	Criterion 4
	Stimulates insulin secretion	Stimulates glucagon secretion	Localized to islet parasympathetic nerves	Released from pancreas by parasympathetic nerve activation	Interference with action alters parasympathetically induced islet hormone secretion
GRP	Yes	No*	Yes	Yes	Yes

*Not consistent in literature.

postganglionic nerve fibers with most nerve cell bodies located in the celiac ganglion and some in the paravertebral sympathetic ganglia (Figure 9.1(a)). Electrical activation of the sympathetic nerves inhibits insulin secretion and stimulates glucagon secretion [31]. The effects of sympathetic nerve activation on insulin and glucagon secretion are partially mediated by the classical neurotransmitter noradrenaline through activation of α-adrenoreceptors, which in turn results in inhibition of adenyl cyclase, with reduced formation of cAMP. However, hyperpolarization with closure of the voltage-sensitive calcium channels and a direct exocytotic action may also be involved.

In addition to noradrenaline, neuropeptides also contribute to sympathetically induced inhibition of insulin secretion. The evidence for this is twofold. First, combined α2- and β-adrenoreceptor blockade by yohimbine and propranolol does not prevent the effect of sympathetic activation to inhibit basal insulin secretion. Second, exogenous noradrenaline does not mimic the effect of sympathetic activation to inhibit basal insulin secretion [31]. Two sympathetic neuropeptides, galanin and neuropeptide Y, may mediate these nonadrenergic effects because they (a) are localized to both the islet sympathetic nerve terminals and their neuronal cell bodies in the celiac ganglion, (b) are released from the pancreas in response to electrical activation of the sympathetic nerves, and (c) each inhibit insulin secretion as demonstrated both *in vivo* and *in vitro* [1].

Galanin

Galanin was isolated from the porcine gastrointestinal tract in 1983 and named because of its glycine C-terminus and alanine N-terminus [32]. In most species it is 29 amino acids in length and amidated in its C-terminus. However, the human form is 30 amino acids long and is not C-terminally amidated.

Galanin is a widely distributed neuropeptide both in the central and peripheral nervous systems. In islets, dense galanin innervation was first demonstrated in dogs, and later in other species, including humans [30,32]. However, species differences

exist; for example, islet galanin innervation is more abundant in dogs and cats than in common laboratory animals like rats and mice [32]. In dogs, islet nerves that contain galanin also contain tyrosine hydroxylase as do their neuronal cell bodies in the celiac ganglion [30]. Thus, islet galanin nerves appear to be sympathetic. This hypothesis is supported by the substantial, although not total, loss of pancreatic galanin nerves that develops after chemical sympathectomy with 6-hydroxydopamine. Further evidence comes from the dog, whose pancreatic galanin is released after sympathetic nerve activation, and from the mouse, whose pancreatic galanin content is reduced by exercise stress [30]. Therefore, although galanin may occasionally also be found in certain other nerves, most data suggest that islet galanin is a sympathetic neuropeptide.

Galanin has been demonstrated to potently inhibit basal and stimulated insulin secretion both *in vivo*, as demonstrated in dogs, rats, and mice, and *in vitro*, as shown in isolated rodent and human islets and in perfused rat pancreas. Galanin also stimulates glucagon secretion [32]. The actions of galanin have been shown to be transmitted by signals induced by activation of three different galanin receptor subtypes, called GalR1, GalR2, and GalR3, respectively. All three are G-protein-coupled receptors encoded by different genes [32]. The GalR1 form is expressed in insulin-producing cells and therefore most likely the mediator of the inhibitory effect of galanin on insulin secretion [33]. The mechanism underlying this inhibitory action involves opening of ATP-sensitive potassium channels and inhibition of the cellular uptake of calcium by closure of voltage-sensitive calcium channels through hyperpolarization, although also inhibition of the formation of cAMP through involvement of a pertussis toxin-sensitive G-protein, and through actions on proteins which are of critical importance for the exocytosis of secretory granules have been suggested [32–35].

Functional studies have demonstrated that galanin is released from the dog pancreas during sympathetic nerve activation in a quantity that is sufficient to mimic the inhibition of insulin secretion induced by sympathetic nerve stimulation [30]. These data therefore suggest that galanin

helps mediate sympathetically induced inhibition of insulin secretion. A similar conclusion comes from a study in mice in which two minutes of swimming causes a 50% inhibition of glucose-stimulated insulin secretion [36]. When galanin was immunoneutralized in these mice by pretreatment with a high-titer galanin antiserum, swimming no longer inhibited glucose-stimulated insulin secretion, suggesting that galanin mediated this exercise-induced inhibition of insulin secretion. Further support comes from galanin knockout mice where the inhibitory effect of sympathetic nerve activation of insulin secretion is impaired [37]. Although a galanin receptor antagonist, galantide, exists [38], studies using this approach to prove a role for galanin in sympathetically mediated inhibition of insulin secretion remain to be performed.

Neuropeptide Y (NPY)

NPY was isolated from the porcine brain in 1982 and shown to be of a 36-amino acid residue with tyrosine at both N- and C-termini. It has structural homology with peptide YY (PYY) and pancreatic polypeptide (PP) and is widely distributed in the central and peripheral tissues. In most tissues the peptide is localized to perivascular adrenergic nerve fibers. In the pancreas, NPY-containing nerve terminals have been demonstrated around vessels, in the exocrine portion of the gland, as well as in islets in dogs, pigs, and mice [1,39,40]. NPY is co-localized with tyrosine hydroxylase in most islet nerves, suggesting that it is mainly a sympathetic neuropeptide. This hypothesis is supported by the localization of NPY to nerve cell bodies of the celiac ganglion, which also stain for tyrosine hydroxylase [1,40]. However, some islet nerves that do not contain tyrosine hydroxylase also express NPY, suggesting an additional nonsympathetic function for islet NPY [40]. NPY is released from the pancreas during nerve activation and most studies suggests that NPY inhibits glucose-stimulated insulin secretion, that is, it exerts sympathetic-like effect, both *in vivo* and *in vitro* [1,39–41].

Several NPY receptors exist, all of which are G-protein-coupled with seven transmembrane domains. In insulin-producing cells, it is the Y1 receptor subtype (Y1R) that mediates islet actions of NPY [41]. The mechanism underlying NPY's inhibition of glucose-stimulated insulin secretion involves inhibition of adenylate cyclase which reduces the formation of cAMP [41]. However, NPY also seems to inhibit insulin secretion through a mechanism distal to the formation of cAMP, because insulin secretion stimulated by a cAMP analogue can also be inhibited by NPY [1]. Although the physiologic importance of NPY for islet function remains to be established, there is some evidence that endogenous islet NPY tonically restrains insulin secretion. Thus, immunoneutralization of NPY in isolated islets leads to increased insulin secretion [42], and mice with genetic deletion of NPY have increased insulin secretion [43].

Sympathetic effects and mediation

Sympathetic nerves inhibit insulin and stimulate glucagon secretion. Their activation may help mediate stress-induced changes in islet hormone secretion including the glucagon counterregulatory response to hypoglycemia. These effects may be mediated by the combination of the classical neurotransmitter noradrenaline and the sympathetic neuropeptides (galanin and NPY). All three neurotransmitters can inhibit insulin and stimulate glucagon secretion, thus mimicking the effects of sympathetic activation on islet hormone secretion. In addition, galanin and NPY meet several other of the criteria needed to be classified as a physiologic neurotransmitter (see [30] and Tables 9.1 and 9.3).

Islet sensory neuropeptides

Islets are innervated by sensory, as well as autonomic, nerves. Some sensory nerves, usually the pain fibers, contain the

Table 9.3 Application of the criteria from Table 9.1 for neurotransmitters in sympathetic islet nerves to mediate the inhibition of insulin secretion and stimulation of glucagon secretion which are effects achieved by activation of the sympathetic nerves

NPY	Yes	Yes	Yes*	Yes	Yes

*Also localized to parasympathetic nerves.

neuropeptides calcitonin gene-related peptide (CGRP) and substance P [1,44,45], which allows their localization by immunocytochemistry. These sensory islet nerves innervate mainly the peripheral portions of islets. They travel with the sympathetic nerves from the pancreas, reaching the spinal cord by way of the splanchnic nerves. The neurotoxin capsaicin causes deafferentation of small unmyelinated C-fibers and a substantial reduction of the number of islet CGRP nerves and a more moderate reduction of the number of islet substance P nerves [44]. Such chronic sensory denervation studies have shown that insulin secretion and glucose elimination are both increased in mice [46] and in Zucker diabetic fatty rats [47], suggesting that these sensory nerves tonically inhibit insulin secretion.

Calcitonin gene-related polypeptide (CGRP)

CGRP was originally described in a medullary thyroid carcinoma cell line, where it was found to be encoded in the same gene as calcitonin [45,48]. This gene, which is called the calcitonin complex gene A (*CALCA*) encodes for two different mRNAs, one that is translated to preprocalcitonin and the other translated to the 128-amino acid preproCGRP, which is further processed to α-CGRP. Later, another gene was described, named calcitonin complex gene B (*CALCB*), which encodes for β-CGRP. The α and β CGRPs are both 37-amino acid peptides and have a high degree of homology with each other and with islet amyloid polypeptide (IAPP) and adrenomedullin [48]. CGRP is localized both to the central and peripheral nervous systems. In the latter, it is largely found in sensory nerves. In the pancreas, CGRP nerves are scattered throughout the parenchyma, with particular density along small blood vessels and within islets where neurotransmitter release sites are in close apposition to the endocrine cells [45], suggesting an islet action. Exogenous administration of CGRP inhibits insulin secretion and in isolated islets, this inhibition is accompanied by reduction of the formation of cAMP which is prevented by pertussis toxin and therefore most likely mediated by an inhibitory Gi-protein [45].

CGRP, as well as IAPP, calcitonin, and adrenomedullin, can act through either the calcitonin receptor-like receptor (CRLR) or the calcitonin receptor (CTR). The affinity of these receptors for the different ligands is regulated: three different receptor activity-modifying proteins (RAMPs) govern the specificity of the receptors for the different ligands: RAMP1-transported CRLR is a CGRP receptor, whereas RAMP2- or RAMP3-transported CRLR is an adrenomedullin receptor. IAPP binding is more related to RAMP-transported CTR [49]. Of particular interest for islet physiology is the demonstration that CRLR and the RAMPs are expressed in β cells [49], suggesting that the regulation of RAMP1 expression and function governs the islet influence of CGRP. In conclusion,

CGRP fulfills some, but not all, criteria for a sensory inhibitory islet neurotransmitter.

Substance P

Substance P was discovered in 1931 and is today known to be within the tachykinin family of peptides [50]. It consists of 11 amino acids and is ubiquitously distributed in sensory neurons with its main function involved in pain perception [50]. Immunohistochemistry of mouse and pig pancreas has demonstrated that substance P is expressed in islet sensory nerves [44,51]. It may therefore, together with CGRP, be involved in the regulation of islet function. This hypothesis is supported by the effect of acute capsaicin administration, which releases substance P from the pancreas [51]. The effects of substance P on insulin secretion remain, however, controversial. On one hand, substance P inhibits insulin secretion in mice and rats [52–54], whereas substance P stimulates insulin secretion in the pig pancreas [51]. There is more agreement regarding glucagon secretion: substance P stimulates glucagon secretion in both rats and pigs [51,52,55]. The main and preferred receptor for substance P is the neurokinin 1 receptor (NK1 receptor), which is a G protein-coupled receptor [56]. This receptor is abundantly expressed on α cells, but it has not been convincingly demonstrated to be expressed on β cells [57]. Therefore, although substance P is expressed in islet sensory nerves, controversy persists regarding its physiologic significance for islet hormone secretion.

Summary of present-day knowledge

We know today that the pancreatic islets are innervated by parasympathetic, sympathetic, and sensory nerves. The parasympathetic nerves stimulate insulin and glucagon secretion whereas sympathetic nerves inhibit insulin secretion and stimulate glucagon secretion; the net influence of the sensory nerves is not yet clearly established. We also know that besides the classical neurotransmitters, noradrenaline and acetylcholine, the islet autonomic nerves also release neuropeptides which can also influence insulin and glucagon secretion. PACAP, VIP, and GRP are released from parasympathetic nerves and can stimulate both insulin and glucagon secretion. Galanin and NPY are released from islet sympathetic nerves, can inhibit insulin secretion and stimulate glucagon secretion. CGRP and substance P can be released from islet sensory nerves with mixed effects on insulin and glucagon secretion. Several important questions remain to be answered to fully understand the role of the autonomic nerves in general, and their neuropeptides in particular, in the control of islet function.

Questions for future research

What are the physiologic roles of the islet autonomic nerves?

Although we know the effects on islet hormone secretion of activating autonomic nerves, there is less known about the physiologic conditions that activate these nerves and therefore their physiologic role. It is known that islet parasympathetic nerves are activated in anticipation of meals and early during the ingestive phase of a meal. Thus, they likely contribute to the release of insulin at this very early stage, the so-called cephalic phase of insulin secretion. There is also evidence for a parasympathetic contribution to insulin secretion even after glucose absorption. The contribution of autonomic nerves to meal-induced insulin secretion has been verified in an interventional study in healthy humans in which subjects were served a test meal together with an intravenous infusion of trimethaphan. This substance interrupts ganglionic transmission and therefore simulates autonomic denervation, at least to the extent possible in humans. The study showed that the early (10 min) increase in insulin was reduced by trimethaphan [3]. Thus, the likely physiologic role of islet parasympathetic nerves is to initiate and amplify the early insulin response to meals.

It is also known that pancreatic sympathetic nerves are activated during hypoglycemia. Since activation of these nerves stimulates glucagon secretion, it is likely that they contribute to glucagon counterregulation during hypoglycemia. This contribution was demonstrated in humans by inducing complete ganglionic blockade by trimethaphan during a hyperinsulinemic hypoglycemic clamp. It was found that the glucagon response was severely suppressed, which suggests that autonomic activation makes a major contribution to the glucagon response to hypoglycemia [58]. This autonomic stimulation of glucagon secretion is likely amplified by the direct action of low glucose to stimulate glucagon secretion from the α cells by releasing the α cell from the inhibitory effect the β cell has on it. In addition to these two relatively clear examples of autonomic contributions to islet hormone responses, there are likely others that have not been as carefully defined. In particular, the potential contribution of the sensory nerves needs to be examined in more detail.

What is the contribution of neuropeptides?

The classical autonomic neurotransmitters (acetylcholine for parasympathetic nerves and noradrenaline for sympathetic nerves) mimic many of the effects seen by direct activation of the nerves. However, the neuropeptides may also contribute to the effect of nerve activation, and Table 9.1 shows the criteria needed for acceptance of a neuropeptide as a physiologic neurotransmitter involved in the control of islet function. In Table 9.2 and Table 9.3, these criteria have been applied for the neuropeptides known to be present in parasympathetic and sympathetic nerves, respectively. Although some neuropeptides meet all these criteria, others need more study, particularly in

humans. More generally, there is need for further study of the detailed regulation of small vesicles release (which contain the classical neurotransmitters) versus large dense core vesicles release (which contain the neuropeptides). In particular, do dissociated release mechanisms exist for these two types of vesicles and, if so, are they relevant for the regulation of islet hormone secretion?

Do the autonomic nerves contribute to development of type 2 diabetes?

Insulin resistance is a common feature of type 2 diabetes. Under normal circumstances, a compensatory increase in insulin secretion occurs thereby ensuring the maintenance of normal glucose tolerance. If this β-cell adaptation is insufficient for the degree of insulin resistance, glucose intolerance and eventually type 2 diabetes develop. Several signals may mediate the appropriate increase of insulin release, including circulating glucose and lipids. However, mediation by parasympathetic nerves may also contribute. First, people with insulin resistance have increased circulating levels of pancreatic polypeptide (PP) [59,60], which is a marker for the parasympathetic nerve activity. Second, the hyperinsulinemia of obese rats and mice is reduced after vagotomy [1] and the hyperinsulinemia induced by experimental insulin resistance in humans is reduced by ganglionic blockade [61]. Such studies provide proof of principle that the parasympathetic input to the islet is activated in states of insulin resistance and could, therefore, help prevent the failing insulin secretion in type 2 diabetes. However, further studies are needed to determine the contribution of defects in this parasympathetic pathway to the development of glucose intolerance and type 2 diabetes.

Is islet neurotransmission a therapeutic target for type 2 diabetes?

Due to the potent effects of the autonomic neurotransmitters on insulin secretion, it has been suggested that targeting their neurotransmitter receptors may be a potential therapy for type 2 diabetes. This has been of particular interest in relation to the parasympathetic receptors, since their activation increases insulin secretion. For example, activation of the M3 receptors [5] as well as of the PACAP [62,63], VPAC1 [64,65], and VPAC2 receptors [66] induces insulin secretion. A drawback is, however, that both PACAP and VIP also stimulate glucagon secretion, which would be predicted to aggravate hyperglycemia in type 2 diabetes; therefore this approach has not yet been approved for preclinical trials in humans.

Since the sympathetic neurotransmitters inhibit insulin secretion, interrupting their signals may be a therapeutic target, as has been suggested for α2-adrenoceptors [67]. Finally, the islet sensory nerves have also been proposed as a target for therapy, since sensory deafferentation improves diabetes in ZDF rats [47]. Again, both approaches need to be explored in more detail in preclinical human studies.

Biosynthesis, secretion, and action of glucagon

Pierre J. Lefèbvre

University of Liège, Liège, Belgium

Key points

- The primary structure of glucagon has been remarkably conserved through evolution.
- The glucagon gene encodes for a preprohormone that contains not only glucagon, but several other peptides including GLP-1 and GLP-2.
- Glucagon acts through binding to specific receptors located at the target cell plasma membrane.
- The hepatocyte is the major target of glucagon.
- The control of glucagon secretion is multifactorial.
- Glucagon is the first line of defense against hypoglycemia.
- Glucagon plays a major role in starvation, physical exercise, stress, and the adaptation to extrauterine life.
- Plasma glucagon levels are increased in most forms of diabetes.
- Diabetes can be seen as a "paracrinopathy" of the islets of Langerhans in which both insulin secretory defects and excessive glucagon release play a role.
- Targeting the α cell and glucagon are innovative approaches in diabetes management.

Introduction

Glucagon, discovered in 1923 as a contaminant of early insulin preparations, has long been a neglected hormone.

Glucagon was among the very first polypeptide hormones to be isolated, purified, sequenced, and synthesized. Thanks to the pioneering work of Unger, it was the first polypeptide hormone to become measurable by radioimmunoassay, almost one year before insulin [1,2]. It has served two Nobel Prize winners as a unique tool, which permitted Sutherland and his associates to discover cyclic AMP (cAMP), and Rodbell and his coworkers to discover the role of G-proteins in cell-membrane receptors. Subsequently, the nucleotide sequence of the glucagon gene has been determined and the structure of the human glucagon precursor (preproglucagon) has been deduced. This discovery has been fundamental for clarifying the relationships of glucagon itself with various other peptides derived from the same common precursor, and originating from both the pancreas and the gut. Recent observations suggest that diabetes should be seen as a *paracrinopathy* of the islets of Langerhans in which intra-islet insulin deficiency results in excessive glucagon release from the neighboring α cells and the resulting hyperglucagonemia being a critical factor in the pathophysiology of diabetes [3,4]. A comprehensive bibliography on glucagon up to 1996 can be found in the three volumes of the *Handbook of Experimental Pharmacology* edited by Lefèbvre [5,6] and in the proceedings of a recently held conference [7].

Amino acid composition, extraction, synthesis, and biosynthesis

The amino acid sequence of glucagon isolated from the pancreas of pigs, cattle, and humans is identical. Guinea-pig glucagon is different from all other glucagons that have been isolated, while avian glucagons differ from the predominant mammalian glucagon only by a few conservative replacements. This extreme conservation of primary structure exhibited by glucagon has been considered "at least unusual and at most extraordinary." In fact, it has now been recognized that glucagon belongs to what has been called the pituitary adenylate cyclase-activating polypeptide (PACAP)/glucagon superfamily that includes nine hormones that are related by structure, distribution (especially the brain and the gut), function (often by activation of cAMP), and receptors (a subset of seven *trans*membrane receptors) [8]. The nine hormones include glucagon, GLP-1 (glucagon-like peptide 1), GLP-2 (glucagon-like peptide 2), GIP (gastric inhibitory polypeptide), GRF (growth-hormone-releasing factor), PHM (peptide histidine methionine), PACAP, secretin, and

Figure 10.1 The primary structure of human–porcine glucagon.

VIP (vasoactive intestinal peptide). The origin of the ancestral superfamily members is at least as old as the invertebrates. The most ancient and tightly conserved members are PACAP and glucagon. Evidence to date suggests that the superfamily began with a gene or exon duplication and then continued to diverge with some gene duplications in vertebrates [8]. Mammalian glucagon contains 29 amino acid residues and has a molecular mass of 3485 Da (Figure 10.1). Glucagon can be synthesized *in vitro* by either classic solution synthesis or solid-phase synthesis; in both cases, two substrategies can be used—either fragment assembly or stepwise assembly. All procedures have given highly purified materials that are homogeneous and indistinguishable from natural glucagon by a range of sensitive analytic methods.

The *glucagon gene* consists of six exons and five introns spanning 10 kb; the human glucagon gene is located on chromosome 2 [9]. It encodes for a preprohormone of 180 amino acids that contains not only glucagon but several other peptides including two glucagon-like peptides whose amino acid structures are distinct from, but closely resemble, that of glucagon

and other members of the glucagon superfamily of peptides. The glucagon gene is expressed in the α cells of the islets of Langerhans, the intestinal L cells, and in some parts of the brain. While the functional relevance of glucagon gene expression in the brain is still poorly understood, a clear image has emerged regarding the processing of proglucagon into several bioactive peptides in the pancreas and in the gut (Figure 10.2).

In the pancreas glucagon is the predominant peptide produced, together with glucagon-related polypeptide (GRPP), while the glucagon-like peptides remain in an incompletely processed prohormone fragment. *In the gut* two glucagon-like peptides (GLP-1 and GLP-2) are produced, while glucagon remains, in part, as a prohormone fragment, glicentin. However, glicentin can be further processed to oxyntomodulin and GRPP. Of these peptides of the glucagon super-family, oxyntomodulin and possibly glicentin are implicated in the physiologic negative control of gastric acid secretion.

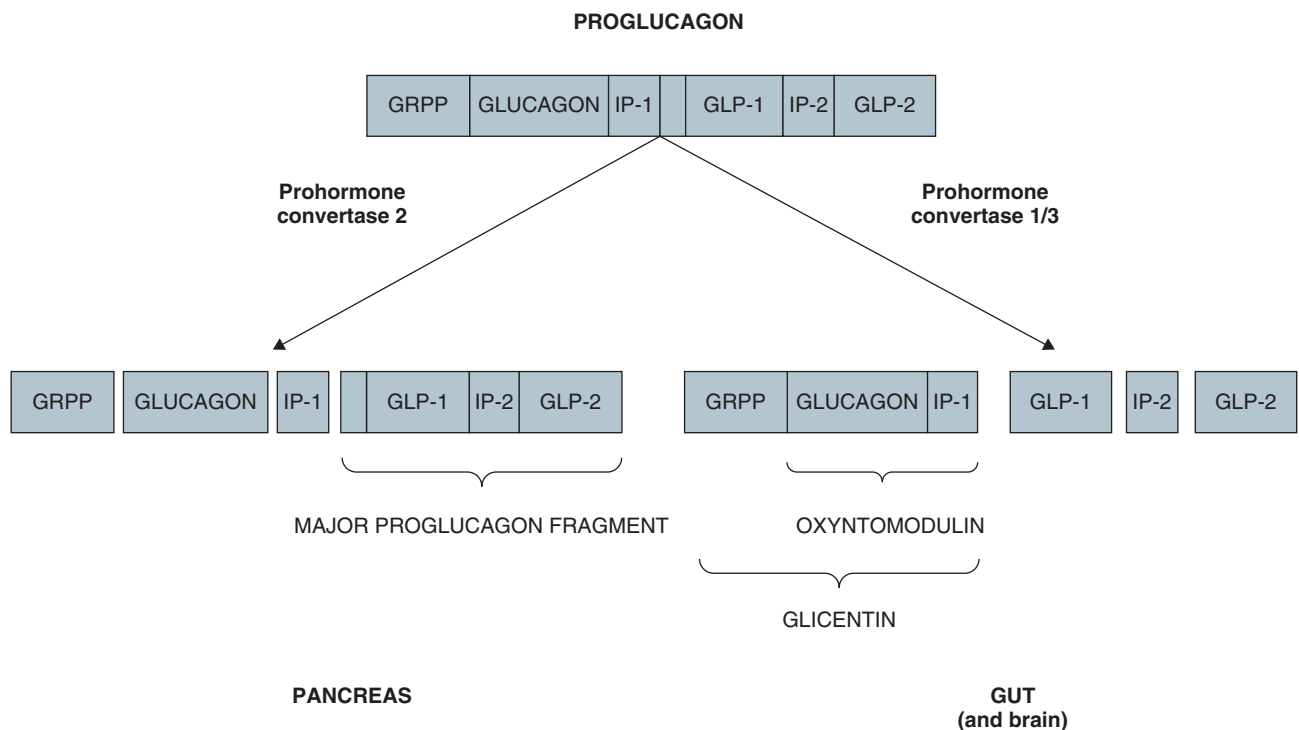
Glucagon-like peptide GLP-1(7-37), a peptide of 31 amino acids, or the equally potent isopeptide GLP-1(7-36), an amide of 30 amino acids, has major insulinotropic action on pancreatic β cells [10,11]. This peptide binds to specific receptors on islet β cells, stimulating cAMP formation, insulin release, proinsulin gene transcription, and proinsulin biosynthesis, all in a glucose-dependent manner. Interestingly, GLP-1 is a strong inhibitor of glucagon secretion. GLP-1 also exerts numerous extrapancreatic actions, including inhibition of food


Figure 10.2 Differential processing of proglucagon in the pancreas and in the gut. In the pancreas, the processing in the α cells is done by the prohormone convertase 2 and the main peptides released are glucagon, GRPP and a so-called "major proglucagon fragment." In the intestinal L cells (as in the brain) the processing is done by the prohormone convertase 1/3 and the main peptides released are GLP-1, GLP-2, glicentin, and oxyntomodulin. IP-1 and IP-2 are intervening peptides.

intake, promotion of satiety, cardioprotection, vasodilation, and possibly beneficial effects on endothelial function and inflammation [12]. GLP-1 is rapidly degraded by the enzyme dipeptidyl-peptidase-4 (DPP-4). As reviewed in Chapter 48, GLP-1 analogues, such as exenatide and liraglutide, and DPP-4 inhibitors, such as vildagliptin, sitagliptin, saxagliptin, linagliptin, and alogliptin are now used in the treatment of type 2 diabetes.

GLP-2 is recognized as a major regulator of intestinal growth and function. Its secretion from the intestinal L cells is essentially stimulated by nutrient intake. It has specific trophic effects on the gut which appear to be mediated by stimulation of mucosal cell proliferation and inhibition of apoptosis and proteolysis [13]. Additional effects of GLP-2 on the digestive tract include stimulation of enterocyte glucose transport and GLUT-2 expression, increased nutrient absorption, reduction of intestinal permeability, stimulation of intestinal blood flow, relaxation of intestinal smooth muscle, and inhibition of gastric emptying and gastric acid secretion [14,15]. Further effects of GLP-2 include stimulation of glucagon release from the islet α cells and modulation of islet adaptation to metabolic stress. GLP-2 has been reported to reduce bone resorption and to significantly increase bone mineral density in postmenopausal women. Preliminary studies suggest a great therapeutic potential of GLP-2 in total parenteral nutrition, short bowel syndrome following major intestinal resection, nonsteroidal drug-induced enteritis, inflammatory bowel disease, ischemic bowel, and so forth. Recently, teraglutide, a degradation-resistant GLP-2 analogue was approved for the treatment of short-bowel syndrome.

Both glucagon and oxyntomodulin are further processed into N-terminal and C-terminal fragments by cleavage at a dibasic site (Arg17-Arg18) [16,17]. The C-terminal fragments are of particular interest: glucagon-(19-29) modulates the plasma membrane calcium flow in the nanomolar range, whereas oxyntomodulin-(19-37) inhibits gastric acid secretion, as does oxyntomodulin itself. Further studies have shown that glucagon processing to glucagon-(19-29) (mini-glucagon) is probably essential for the positive inotropic effect of glucagon on heart contraction. Thus, the concept has emerged that glucagon and oxyntomodulin are first released into the blood and then processed at the level of their respective targets into the corresponding biologically active C-terminal fragments. Interestingly, mini-glucagon inhibits insulin secretion at picomolar concentrations. It has been proposed that mini-glucagon acts as a local inhibitory regulator of insulin release by turning off the main external calcium source for islet β cells via a specific receptor linked to ion channels that control cell polarity [18,19].

The tissue-specific liberation of proglucagon is controlled by cell-specific expression of enzymes known as prohormone convertases (PC). A major defect in the processing of proglucagon to mature pancreatic glucagon is seen in the PC2 knockout mouse. These animals exhibit mild hypoglycemia and hyperplasia of the α cells in the islets of Langerhans [20,21]. These abnormalities are corrected by glucagon replacement via a micro-osmotic pump [22]. Numerous studies have recently investigated the transcriptional regulation of α-cell differentiation and that of the proglucagon gene [7,23–25]. The differentiation of α cells and the maintenance of α-cell function are influenced at several stages during development and in the maturing islet. Several transcriptional factors such as neurogenin 3 (Ngn 3), pancreatic duodenal homeobox 1 (Pdx-1) and regulatory factor X6 (Rfx6) are crucial in the determination of the endocrine cell fate. Other transcription factors such as aristaless-related homeobox (Arx) and forkhead box A2 (Foxa2) are implicated in the initial or terminal differentiation of α cells. On the other hand, proglucagon transcription, and therefore the maintenance of α-cell function, is regulated by several factors, including forkhead box A1 (Foxa1), paired box 6 (Pax6), brain 4 (Brn4), and islet-1 (isl-1) [23]. Interestingly, recent studies have shown that "endocrine cell reprogramming" is possible with conversion of pancreatic α cells into cells displaying a β-cell phenotype, thus possibly offering a totally new avenue for the treatment (or cure ?) of diabetes [24,25].

Physiologic effects of glucagon

Glucagon acts through binding to specific receptors located at the target cell plasma membrane. The major common effect of glucagon is to activate adenylate cyclase and to increase the intracellular production of cAMP. There is considerable evidence that binding of glucagon to its receptor activates an intermediate transduction process that involves the participation of guanosine triphosphate (GTP), divalent cations, and adenosine (or other similar natural substances). The glucagon receptor has been characterized; it is a 62-kDa glycoprotein that contains at least four N-linked oligosaccharide chains and intramolecular disulfide bonds. The use of various mutated glucagon receptors has resulted in the demonstration that a five-amino acid domain within the membrane proximal portion of the COOH-terminal tail is required for cell surface expression; that most of the COOH-terminal tail is not required for glucagon binding, cAMP accumulation, or Ca2+ mobilization; and that phosphorylation of the COOH-terminal tail is required for glucagon-stimulated receptor internalization [26]. Further, positively charged residues at positions 12, 17, and 18 of the glucagon molecule contribute strongly to the stabilization of the binding interaction with the glucagon receptor that leads to maximal biologic potency [27].

Elimination of signaling through the glucagon receptor has been investigated in depth in mice [28]. Glucagon receptor knockout (GcgR-/-) mice are viable but exhibit a number of striking phenotypes including an expected mild hypoglycemia and improved glucose tolerance. Other consequences include increase in total pancreatic weight, marked α-cell hyperplasia and extreme elevations of circulating plasma levels of glucagon and GLP-1. These mice also exhibit multiple defects in islet cell phenotypes implying a complex, and still poorly understood,

role of glucagon in islet development. Another striking observation is an increased susceptibility of GcgR-/- hepatocytes to apoptotic injury, suggesting that glucagon signaling is essential for cell survival. Furthermore, GcgR-/- hepatocytes exhibit profound defects in lipid oxidation and accumulate excessive lipid during fasting. Last, GcgR-/- mice exhibit reduced fetal weight, increased fetal demise at the end of gestation and abnormalities in the placenta suggesting that glucagon signaling is essential in fetal and placental development. The most striking effect of elimination of glucagon signaling is the lack of diabetes after alloxan or streptozotocin destruction of islet β cells in GcgR-/- mice [29], as discussed later.

The hepatocyte is a major target cell of glucagon. The main effect of glucagon on the liver is to increase glucose output, an effect that results from inhibition of glycogen synthesis and stimulation of liver glycogenolysis and gluconeogenesis. Basal glucagon is important in maintaining hepatic glucose production during a prolonged fast and gluconeogenesis and glycogenolysis are equally sensitive to stimulation by glucagon *in vivo* [30,31]. Studies using mass isotopomers suggest that low doses of glucagon stimulate only nongluconeogenic glucose release while higher doses stimulate both the gluconeogenic and nongluconeogenic pathways [32]. Interestingly, hyperglucagonemia stimulated endogenous glucose production during fructose infusion, but this effect was not secondary to stimulation of gluconeogenesis but rather to channeling of glucose-6-phosphate toward systemic release [33,34]. There is ample evidence that most of these effects are mediated by cAMP, but the possibility has been raised that part of the glycogenolytic effect of glucagon may occur by a cAMP-independent mechanism. *In vitro* studies have shown that pulsatile delivery of glucagon is more efficient than continuous exposure to stimulate hepatic glucose production. Similarly, pulsatile delivery of glucagon in humans has greater effects in stimulating endogenous glucose production than continuous infusion. Furthermore, when both insulin and glucagon are delivered intermittently and out of phase, the greater effect of glucagon in stimulating glucose production prevails over the greater effect of insulin in inhibiting this parameter [35]. Another major effect of glucagon on the liver is to stimulate ketogenesis, which depends upon both the flux of free fatty acids (FFA) into the liver and the pathway status of this organ, which is influenced in a crucial manner by the glucagon/insulin ratio in the blood perfusing the liver [36]. Further, a high glucagon/insulin ratio increases the intracellular level of cAMP, reduces glycolysis and acetyl-CoA carboxylase activity, and reduces the intracellular concentration of malonyl-CoA. This fall in malonyl-CoA brings fatty acid synthesis to a halt and causes derepression of the enzyme carnitine acyltransferase such that incoming fatty acids (made abundant through stimulation of lipolysis) are efficiently converted into the ketone bodies acetoacetate and 3-hydroxybutyrate.

The effects of glucagon on the adipocyte markedly depend upon the species considered. Although glucagon is a potent lipolytic hormone in birds and in rodents, its effects on the human adipose cell have long been disputed. Recent investigations have shown that glucagon is indeed strongly lipolytic in the human adipocyte *in vitro*, but that this effect is difficult to demonstrate using incubation of adipocytes or adipose tissue pieces because glucagon is rapidly destroyed by a proteolytic activity associated with those cells. When perifusion techniques are used, the lipolytic effect of glucagon on human adipocytes can easily be demonstrated. In humans in the presence of somatostatin-induced insulin deficiency, pulsatile glucagon exerts greater effects than its continuous delivery not only on blood glucose, as mentioned earlier, but also on plasma FFA, glycerol, and 3-hydroxybutyrate levels [37]. Interestingly, in the older population the lipolytic and ketogenic, but not the hyperglycemic, responses to pulsatile glucagon are significantly reduced [37]. In healthy volunteers , moderate hyperglucagonemia undoubtedly stimulates the rate of appearance in the plasma of both glycerol and FFA [38], while, in contrast, microdialysis studies failed to demonstrate a lipolytic effect of glucagon [39,40]. It has been recently suggested that the lipolytic of glucagon in humans is mediated by FGF-21 (fibroblast growth factor 21) [41].

Other effects of glucagon

Other metabolic effects of glucagon include modification of the circulatory pattern of plasma amino acids (partly due to the stimulation of gluconeogenesis), a reduction in circulating levels of cholesterol and triglycerides, and a stimulation of fibrinogen formation. Glucagon also stimulates insulin release, but the physiologic character of this effect is questionable [42]. It has a major role, together with insulin, in liver regeneration [43]. Under certain circumstances, glucagon increases renal blood flow and glomerular filtration rate, and promotes renal loss of sodium and other ions [44]. At pharmacologic doses, glucagon stimulates adrenal catecholamine release, an effect that has been used for the diagnosis of pheochromocytoma. Combining glucagon stimulation and clonidine suppression testing has given a sensitivity of 100% and a specificity of 79% for the diagnosis of pheochromocytoma [45]. Glucagon also exerts positive inotropic and chronotropic effects on the heart [46], effects that may be useful, for instance, in treating the cardiodepressive manifestations of poisoning by β-receptor blocking agents. Glucagon and several of its analogues, like glucagon-(1-21), which is devoid of metabolic effects, exert a potent smooth-muscle spasmolytic action, sometimes used for various diagnostic procedures or for therapeutic applications like bronchospasm [47].

Control of glucagon release

There is considerable evidence that the control of glucagon secretion is multifactorial and involves direct effects of

nutrients on α-cell stimulus-secretion coupling as well as paracrine regulation by insulin, somatostatin and, possibly, other mediators such as zinc, γ-amino-butyric acid (GABA) or glutamate [48,49]. Glucagon secretion is also regulated by circulating hormones and the autonomic nervous system [50,51]. Table 10.1 lists the factors and conditions demonstrated as stimulators of glucagon secretion. The main physiologic or pathophysiologic stimulators of glucagon release are hypoglycemia (insulin-induced, associated with starvation or intense muscular exercise), hyperaminoacidemia (the rise in plasma glucagon levels after a balanced meal is probably due mainly to amino acid-induced glucagon release), stimulation of the adrenergic system (stress, exercise, and possibly hypoglycemia), and stimulation of the vagal system, which together with hormones like GIP and CCK-PZ probably participate in the mixed meal-induced glucagon rise.

The factors and conditions associated with inhibition of glucagon release are listed in Table 10.2. The main physiologic inhibitors of glucagon release are probably hyperglycemia and hyperinsulinemia (in a glucose-rich or carbohydrate-rich meal) and high circulating levels of FFA. It has been suggested that glucokinase may serve as a metabolic glucose sensor in pancreatic α cells, and hence constitute a mechanism for direct regulation of glucagon release by extracellular glucose. Intra-islet insulin, glucagon, and somatostatin release have been shown to be interrelated [52]. In such paracrine mechanisms,

further data suggest that the oscillatory pattern of islet hormone release may be particularly important [53,54]. Using isolated perifused human islets, it has been shown that glucose generates coincident insulin and somatostatin pulses and clear antisynchronous glucagon pulses [55]. The periodicity of these pulses is 7 to 8 min. The fact that these pulses occur in isolated islets demonstrates that their origin is the islets themselves and independent of external metabolic, hormonal, or neuronal signals. The nature of the intra-islet signal(s) coordinating the secretion of the various endocrine cells of the islets of Langerhans is still the subject of intense investigation [56–61].

Some aspects of glucagon physiology and pathophysiology

Glucagon as a counterregulatory hormone

Numerous studies have shown that the liver is the main site at which moment-to-moment control of glucose homeostasis takes place and that in normal humans glucagon is the major glucose counterregulatory hormone. By antagonizing the suppressive effects of insulin on glucose production and by stimulating glucose production when appropriate, glucagon not only defends the organism against hypoglycemia, but also restores normoglycemia if hypoglycemia occurs. Perturbation of the mechanisms controlling hypoglycemia-induced glucagon

Table 10.1 Stimulators of glucagon release

Substrates	Hypoglycemia or cytoglycopenia (2-deoxyglucose), low circulating levels of FFA, most amino acids, fumarate and glutamate
Neural factors	Stimulation of adrenergic and cholinergic nervous systems, stimulation of ventromedial (and ventrolateral?) hypothalamus
Local transmitters or factors	Epinephrine, norepinephrine, acetylcholine, dopamine, VIP, neurotensin, bombesin, substance P, prostaglandins, cAMP, β-endorphin
Hormones	Gastrin, cholecystokinin-pancreozymin (CCK-PZ), GIP, growth hormone
Ions	Total absence of calcium; lack of phosphate, lack of magnesium, presence of potassium (?)
Pharamacologic	Furosemide, scorpion venom, phospholipase A2, L-dopa, clonidine, oxymetazoline, clonbuterol
Environmental factors	Starvation, exercise, stress, balanced meal

Note: In this, "?" indicates uncertain or conflicting data.

Table 10.2 Inhibitors of glucagon release

Substrates	Hyperglycemia, high circulating levels of FFA (and ketone bodies)
Local transmitters or factors	Serotonin, somatostatin
Hormones	Insulin, secretin, GLP-1, estrogens, amylin
Ions	Calcium, magnesium, zinc (?)
Pharmacologic	Atropine, β-receptor blocking agents, α2-receptor blocking agents, indomethacin, meclofenamate, ibuprofen, diphenylhydantoin, procaine, diazepam, phenformin, somatostatin analogues, pramlintide, exenatide, liraglutide, DPP-4 inhibitors (vildagliptin, sitagliptin, saxagliptin, linagliptin, alogliptin)
Environmental factors	Carbohydrate meal, pregnancy

Note: In this table, "?" indicates uncertain or conflicting data.

release in some diabetic patients markedly increases the risk of severe hypoglycemia in these subjects. Other hormones, such as epinephrine (acutely) and growth hormone and cortisol (more slowly), participate in the counterregulation of the effects of insulin, but careful clinical observations suggest that indeed glucagon is the first line of defense against hypoglycemia [62].

Glucagon in exercise

Glucagon levels increase progressively during prolonged exercise [63], during which blood glucose remains relatively constant thanks to a fine balance between muscle glucose uptake and liver glucose production. Although a rise in plasma glucagon does not appear to be essential for increased glucose production during exercise, the presence of glucagon does appear to be necessary.

Glucagon in stress

Hyperglucagonemia is a classic feature of stress [64]. It occurs mainly as a result of the β-adrenergic stimulation associated with stress and undoubtedly contributes to the hyperglycemia, which is a classical finding in this condition.

Glucagon in starvation

Starvation is accompanied by a decline in circulating insulin and a moderate rise in plasma glucagon [65]. The main effects of glucagon during starvation are at the liver, where it contributes to the maintenance of continuous liver glucose output (initially by stimulating glycogenolysis, and later by promoting gluconeogenesis) and the induction of ketogenesis. Whether glucagon contributes to the stimulation of adipose tissue lipolysis during starvation is still disputed.

Glucagon and adaptation to extrauterine life

A significant rise in plasma glucagon occurs soon after birth in all species investigated so far, which suggests that glucagon has a crucial role in neonatal glucose homeostasis [66]. Furthermore, an important role of glucagon in thermogenic regulation has been suggested.

Glucagon and diabetes

Plasma levels of glucagon have been found to be increased in all experimental and clinical forms of diabetes mellitus. This disturbance undoubtedly contributes to the hyperglycemia of the disease and excessive ketogenesis of diabetic coma. Numerous studies have shown that failure of glucagon suppression contributes to postprandial hyperglycemia in type 1 [67] and type 2 [68,69] diabetes. Impaired glucagon suppression contributes with impaired insulin release to the excessive blood glucose levels in early type 1 diabetes [70], in subjects with impaired glucose tolerance [71,72], and in patients with ketosis-prone atypical diabetes [73,74]. Morphologic studies have established that the main abnormality in the islet cell population of diabetes is a decrease in the β cells with a relative expansion of the α-cell mass [75].

The proposal of Unger and Orci to consider diabetes as a "paracrinopathy" of the islets of Langerhans [3] is based on the concept that the very high concentrations of insulin normally reached inside the stimulated islet exerts, directly or by proxy, a major inhibitory effect on glucagon secretion from the neighburing α cells. Conversely, a reduction in intra-islet insulin concentrations would permit glucagon release from the α cells. Disruption of this mechanism is proposed as a key factor in the pathophysiology of diabetes [76]. This concept is supported by recent data on the micro-anatomy of the islets of Langerhans [74,77]. In type 1 diabetes, α cells lack constant action of high insulin levels from juxtaposed β cells. Replacement with exogenous insulin subcutaneously injected does not approach the paracrine levels of insulin, except with high doses that "overinsulinize" the peripheral insulin targets, thereby promoting glycemic volatility [3]. In type 2 diabetes, the α-cell dysfunction may result from the failure of the juxtaposed β cells to secrete the first phase of insulin or from the loss of the intra-islet pulsatile secretion of insulin. Observations made in experimental diabetes in minipigs [78] and recently confirmed in human type 2 diabetes [79] are in support of the second mechanism.

Inhibition of glucagon secretion markedly improves experimental diabetes in rodents [80] and knockout of the glucagon receptor makes rodent models of insulin-dependent type 1 diabetes thrive without insulin [29]. The critical role of glucagon action in the liver in diabetes has been demonstrated by expressing glucagon receptors in livers of glucagon receptor-null (GcgR-/-) mice before and after β cell destruction by high doses of streptozotocin [81]. Wild-type mice developed fatal diabetic ketoacidosis after streptozotocin, whereas GcgR-/- mice remained clinically normal without hyperglycemia, impaired glucose tolerance, or hepatic glycogen depletion. Restoration of receptor expression using adenovirus containing the GcgR cDNA restored hepatic GcgR, phospho-cAMP response element binding protein (P-CREB) and phosphoenol-pyruvate carboxykinase, markers of glucagon action rose dramatically and severe hyperglycemia appeared. When GcgR mRNA spontaneously disappeared 7 days later, P-CREB declined and hyperglycemia disappeared. In this experimental setting, the metabolic manifestations of diabetes cannot occur without glucagon action, and once present, disappear promptly when glucagon action is abolished.

These observations strongly suggest that targeting the α cell and glucagon are innovative approaches in diabetes management. Compounds such as pramlintide and GLP-1 agonists reduce glucagon release and this is considered an important component of their antidiabetic action (see Chapter 48). On the other hand, numerous glucagon antagonists, either peptidic or nonpeptidic, have been indentified and some have entered clinical trials. However, marked inhibition of glucagon signaling may result in α-cell hyperplasia, increased mass of the pancreas, increased susceptibility to hepatosteatosis and hepatocellular injury, and an increased risk of hypoglycemia [82]. Further studies in normal and diabetic subjects should identify the

extent to which reduction of glucagon signaling produces a compelling therapeutic benefit without incurring a risk of adverse events.

The glucagonoma syndrome

The glucagonoma syndrome is a rare disorder associating necrolytic migratory erythema, cheilosis, usually mild diabetes mellitus, anemia, weight loss, venous thrombosis, and, frequently, neuropsychiatric symptoms [83].

CHAPTER 11

Incretin physiology in health and disease

Juris J. Meier and Michael A. Nauck

Division of Diabetes and Gastrointestinal Endocrinology, St. Josef-Hospital, Ruhr-University, Bochum, Germany

Key points

- The postprandial augmentation of incretin hormones by gastrointestinal hormones is called the incretin effect.
- In humans, gastric inhibitory polypeptide (GIP) and glucagon-like peptide 1 (GLP-1) are the major incretin hormones.
- GLP-1 stimulates insulin secretion, suppresses glucagon, delays gastric emptying, and inhibits food intake.
- GIP stimulates insulin secretion, but even slightly stimulates glucagon release.
- A deficit in incretin stimulation is characteristic of patients with type 2 diabetes. This is largely attributable to the reduced insulinotropic effect of GIP.
- The defects in the incretin system in patients with type 2 diabetes are likely a consequence rather that the cause diabetes.

The incretin effect in health

The idea that gastrointestinal factors contribute to the control of postprandial glucose regulation dates back to the beginning of the twentieth century, when Moore and colleagues reported reductions in glucosuria after the oral administration of gut extracts in patients with juvenile diabetes [1]. Even though it is questionable whether these glucose-lowering effects were really attributable to the incretin activity of the extract (which is unlikely, because most gastrointestinal peptide hormones are inactivated by the gastric acid), this report can be considered as the first description of an incretin-like effect. The term "incretin" was coined in 1932 by La Barre to describe a putative substance from the upper gut mucosa, which lowers glucose without activating exocrine secretion [2,3]. At this early time period, various reports about glucose-lowering activities of gut extracts had appeared. However, probably owing to the variations in the purity of these extracts, the results of these experiments were quite heterogeneous, and the idea that gut hormones contribute to glucose regulation was not explored further until the 1960s [3].

The development of the first radioimmunoassay for insulin in 1962 by Berson and Yallow opened up a new era in metabolic research. Elrick and colleagues [4] and McIntyre and colleagues independently reported that oral administration of glucose led to significantly higher increments in insulin secretion than intravenous glucose administration [5], thereby suggesting the existence of gut-derived factors that augmented insulin secretion, that is, an "incretin effect" (Figure 11.1). While these initial studies had therefore already demonstrated some incretin activity in humans, it was still difficult to quantify the respective contribution of this effect to the overall postprandial rise in insulin levels, because the circulating plasma glucose concentrations after i.v. glucose injection significantly exceeded those after oral glucose administration, thereby confounding direct comparisons of the respective insulin concentrations. Therefore, Nauck and colleagues developed the "isoglycemic clamp technique" to quantify the contribution of the incretin effect [6] (Figure 11.2). In these experiments, glucose was first administered by mouth, and the plasma glucose rises were recorded at 5-min intervals. On a second day, glucose was administered intravenously, and the respective glucose infusion rates were varied to exactly copy the glucose concentration pattern of the first experimental day. By these means, it was possible to compare the rises in insulin and C-peptide concentrations at identical plasma glucose level [6]. The incretin effect was then calculated by the equation

Incretin effect

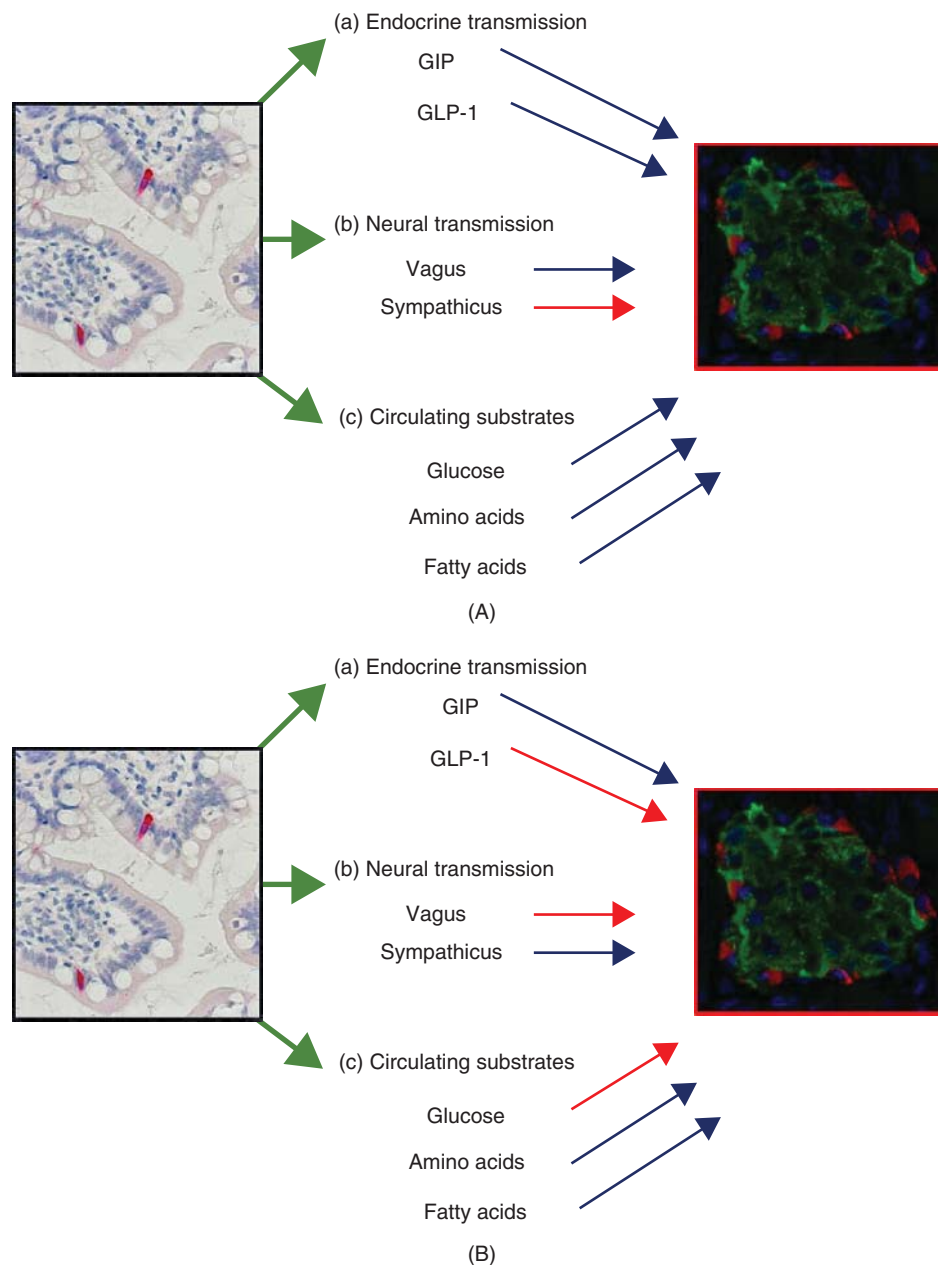
$$= \frac{(\text{AUC}_{\text{oral glucose}} - \text{AUC}_{\text{intravenous glucose}})}{\text{AUC}_{\text{oral glucose}}} \, 100 \, [\%],$$


Figure 11.1 The incretin effect on insulin (a) and glucagon (b) secretion. Following oral administration of nutrients, islet hormone secretion is modulated by (A) the incretin hormones GIP and GLP-1, (B) the sympathetic and parasympathetic nervous system, and (C) the circulating substrates glucose, amino acids, and free fatty acids. Stimulatory actions have been denoted with blue color, inhibitory actions are indicated by red color. Source: Adapted from Creutzfeldt 1979 [98]. Reproduced with permission of Springer. (For a color version of this figure, please see color plate section.)

based on the integrated incremental responses (AUCs) of insulin or C-peptide concentrations or of insulin secretion rates derived by deconvolution of C-peptide concentration-time curves.

Based on these studies, it was estimated that the incretin effect contributed between 27.6% and 62.9% to the overall increments in C-peptide levels after oral glucose ingestion [6]. It was also demonstrated that the "size" (i.e., the percentage contribution) of the incretin effect increased with greater amounts of glucose being administered [6]. Because insulin is subject to considerable first-pass clearance by the liver, the C-peptide-based calculation was considered to be more accurate than the calculation using insulin concentrations. In fact, hepatic insulin clearance is significantly reduced by oral, but not by intravenous glucose administration, meaning that calculations based on insulin levels might lead to an over-estimation of the incretin effect.

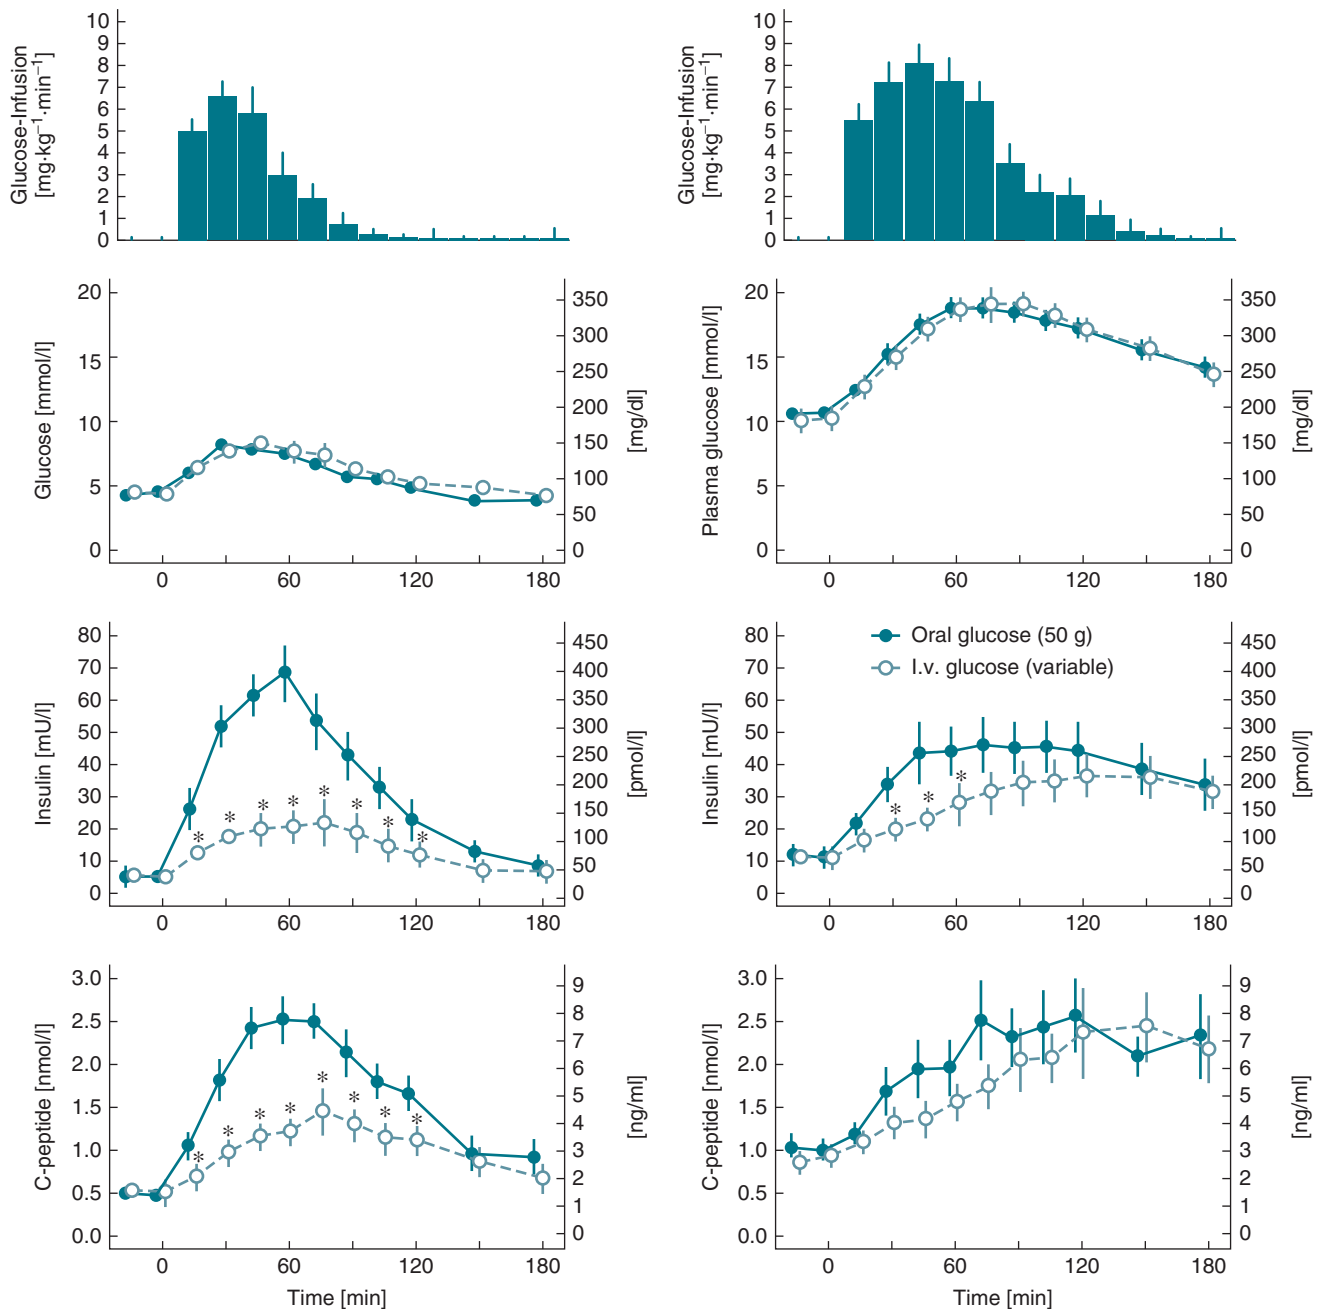
While augmentation of insulin secretion is clearly the most prominent action of the incretin hormones, there also appears


Figure 11.2 The "incretin effect in patients with type 2 diabetes (right panels) and healthy control subjects. The panels show the respective glucose infusion rates as well as plasma concentrations of glucose, insulin, and C-peptide after oral (50 g) and "isoglycemic" intravenous glucose administration in healthy subjects (left panels) and patients with type 2 diabetes (right panels). The difference in incremental C-peptide levels between the experiments with oral and intravenous glucose administration constitutes the incretin effect. In patients with type 2 diabetes, incretin stimulation is markedly diminished. Source: Nauck 1986 [93]. Reproduced with permission of Springer.

to be an effect on glucagon secretion (Figure 11.1). Thus, when glucagon levels after oral and isoglycemic intravenous glucose administration were directly compared, the suppression of glucagon levels was found to be greater after intravenous compared to oral glucose administration [7]. This finding is surprising given the glucagonostatic actions of GLP-1 [8]. However, it appears that these glucagon-lowering effects of GLP-1 are outweighed by the glucagonotropic actions of GIP and potentially GLP-2 [9]. Indeed, when GIP was exogenously co-infused along with GLP-1, the GLP-1-induced suppression of glucagon was completely abolished [10]. Therefore, the net incretin effect on glucagon levels appears to be a modest stimulation of α-cell secretion under normal conditions.

Although the quantification of the incretin effect based on the isoglycemic clamp technique has been accepted as a reference standard for most subsequent studies, a couple of methodological caveats need to borne in mind. Thus, matching circulating plasma glucose concentrations with oral and intravenous glucose administration inevitably results in differences in the amount of glucose being administered on both occasions. Thus, typically ~20–25 g of i.v. glucose were required to reach isoglycemia with 50 g of glucose ingested orally [6]. One might therefore argue that the study design could overestimate the incretin effect due to the different amounts of glucose being administered [11]. Along this line, another argument to consider is the fact that the oral glucose load engages pancreatic β cells through various mechanisms (direct stimulation by circulating glucose, afferent neutral signals, and humoral stimulation by incretin hormones), whereas i.v. glucose represents a single β-cell stimulus. It seems conceivable that under conditions of a general impairment of β-cell mass or function the relative impairment in insulin secretion might be greater with the large combined stimulus (oral glucose) than with the smaller stimulus (i.v. glucose) [11]. It is also important to bear in mind that the estimation of the incretin effect based on isoglycemic clamp experiments is not necessarily representative of the postprandial situation, because the potential contributions of the fat and protein components of a typical mixed meal and other gastrointestinal hormones with insulinotropic effects released by these food components are not taken into account. In line with this, studies in humans have demonstrated significant incretin effect after oral fat or amino acid ingestion as well [12,13]. Finally, variations in the rate of gastric emptying may alter the patterns of insulin secretion after oral glucose ingestion, independent of incretin activity.

Other groups have therefore applied other techniques, such as a relative comparison of insulin secretion after oral glucose ingestion during fixed hyperglycemia at 8 and 10.5 mmol L^{-1} in a single experiment [14]. However, such study design does not take into account the typical postprandial changes in plasma glucose concentrations.

Taken together, the quantification of the incretin effect is complex and can be potentially confounded by various factors. Despite various limitations, the isoglycemic clamp technique still seems to represent the most appropriate measure of the incretin effect.

Secretion of incretin hormones

The mucosa of the intestinal tract harbors a large number of endocrine cells that give rise to various peptide hormones. These include cholecystokinin, motilin, secretin, gastrin, gastric inhibitory polypeptide (GIP, also referred to as glucose-dependent insulinotropic polypeptide), glucagon-like peptide 1 (GLP-1), glucagon-like peptide 2, and peptide YY [15].

The abundance of endocrine cells is greatest in the small intestine and in the rectum [16]. At physiologic plasma levels, incretin activity has been demonstrated for GIP and GLP-1 [8,17,18]. Plasma concentrations of GIP rise ~10–15 min after meal ingestion from baseline levels of ~10–15 pmol L^{-1} and reach peak concentrations of ~150–500 pmol L^{-1}, depending on meal size and composition [6,18,19]. For GLP-1, fasting concentrations range between 2 and 15 pmol L^{-1}, and postprandial concentration between 15–45 pmol L^{-1} have been described [18–21]. When GIP and GLP-1 were infused intravenously at their typical postprandial concentrations, glucose-stimulated insulin secretion was augmented in a similar fashion as seen after oral glucose ingestion, thereby suggesting that the insulinotropic activity of these hormones mediates the physiologic incretin effect to a near-total extent [18].

GIP has been demonstrated to originate from intestinal K cells, which are located throughout the small and large intestine, with a higher cell density towards the duodenum and jejunum [15]. Morphologically, L cells are characterized by a polarized shape, with an apical surface contacting the gut lumen and a basolateral membrane facing the capillary walls. Secretion of GIP is stimulated by carbohydrates, especially glucose and galactose, and certain amino acids [16]. The observation that glucose-induced GIP secretion can be abolished by the administration of the non-selective sodium-glucose co-transporter (SGLT) inhibitor phlorizin indicates that GIP secretion is linked to the absorption of glucose through the enterocytes rather than to the mere presence of nutrients inside the gut lumen [22].

Furthermore, expression of Kir6.2, Sur1, SGLT-1, GPR40, GPR119, and GPR120 was detected on rodent K cells, suggesting a potential modulation of GIP secretion through sulfonylureas and various G-protein receptor ligands [23]. However, increased GIP plasma concentrations have not been described in patients treated with sulfonylurea compounds, thereby challenging the physiologic importance of these receptors [24]. More recently, expression of somatostatin receptors (Sstrs) Sstr2, Sstr3, and Sstr5, and cannabinoid receptor type 1 (Cnr1, CB1) was detected on murine K cells, and inhibition of GIP secretion by somatostatin and the CB1 agonist methanandamide was observed in primary K cells [25]. The active peptide hormone GIP comprises 42 amino acids and an amidated C-terminus and is yielded through posttranslational processing of a larger precursor peptide (proGIP) [16]. The second incretin hormone, GLP-1, originates from intestinal L cells, which also give rise to secretion of peptide YY as well as GLP-2 and other proglucagon cleavage products. The distribution of L cells is heterogeneous throughout the different proportions of the gut with an increasing frequency of L cells being found in the distal parts of the colon and rectum [16,26]. Interestingly, co-expression of GIP and GLP-1 has been demonstrated in a substantial proportion of enteroendocrine cells [26]. The peptide GLP-1 results from proteolytic cleavage of the proglucagon precursor protein by the enzymes prohormone convertase 1/3. The peptides enteroglucagon (glicentin), GLP-2, and peptide

tyrosine tyrosine (PYY) are further intestinal proglucagon cleavage products [27]. GLP-1 is secreted in two distinct forms, an amidated form GLP-1 (7-36) amide, and a glycine-extended form GLP-1 (7-37). The amidated form appears to be more abundant [27]. The biologic activity of these forms has been found to be rather similar [16].

In humans, GLP-1 secretion is enhanced by glucose, triglycerides as well as (to a lesser degree) various amino acids *in vivo* [16]. The mechanisms of GLP-1 secretion have been further examined in an intestinal L-cell line, called GLUTag cells, as well as in primary rodent L-cell cultures [28]. In these experimental models, expression of the sulfonylurea receptor subunits Kir6.2 and SUR1 as well as glucokinase have been detected [29]. Furthermore, stimulation of GLP-1 release through SGLT1 transporters has been suggested [29]. There is also wide evidence for a role of G-protein coupled receptors (GPRs), especially GPR 40, GPR 120, and GPR 119, in GLP-1 secretion [29]. These receptors have been demonstrated to be of particular importance for fatty acid-induced GLP-1 secretion. Stimulation of GLP-1 secretion by bile acids has also been reported in different models. These effects have been suggested to be mediated through the G protein-coupled receptor TGR5, with subsequent rises in intracellular cAMP levels [30].

Various studies in rodent models have suggested that artificial sweeteners, such as saccharin, acesulfame potassium, d-tryptophan, and sucralose, also stimulate GLP-1 release by a newly discovered group of sweet taste receptors [31]. Human studies using the sweet taste receptor T1R2/T1R3 antagonist lactisole have confirmed a physiologic role of these receptors in GLP-1 secretion [32].

There might also be a paracrine inhibitory effect of locally produced somatostatin on L-cell secretion. Finally, recent studies in rodents have suggested a stimulation of GLP-1 release by interleukin-6 (IL-6) [33].

Degradation and elimination of incretin hormones

Following their intestinal secretion, the incretin hormones GIP and GLP-1 are subject to rapid proteolytic cleavage by the enzyme dipeptidyl-peptidase 4 (DPP-4) [34]. DPP-4 can be found throughout the vascular endothelium as well as circulating in the plasma [35]. Because endogenously secreted GLP-1 enters the intestinal capillary network first and is subsequently delivered into the portal venous circulation, only a minor proportion of GLP-1 reaches the systemic circulation in its intact form GLP-1 (7-36) amide, whereas ~85% of the total GLP-1 concentration in the peripheral circulation is found in the (largely) inactive form GLP-1 (9-36) amide [36]. Thus; ~75% of the secreted GLP-1 are inactivated already within the gut, and an additional 40–50% of the remaining GLP-1 undergo degradation during the first liver passage [36].

It has also been suggested that another circulating enzyme, neutral endopeptidase 22.11, contributes to the degradation of GLP-1 to a large extent (up to 50%) [37]. While proteolytic degradation is therefore apparently the most critical step in the inactivation of GLP-1, renal filtration is driving the final elimination of the intact peptide as well as the major metabolites [38]. The mechanisms of renal handling of GLP-1 seem to involve both glomerular filtration and tubular uptake and catabolism [38]. In line with this, human studies have revealed increased plasma concentrations of GLP-1 in patients with renal impairment [38]. The plasma half-life of GLP-1 was calculated as 2.3 ± 0.4 min for the intact peptide and 3.3 ± 0.4 min for the major metabolite GLP-1 (9-36) amide. The corresponding metabolic clearance rates were 2.42 ± 0.45 L min^{-1} and 0.64 ± 0.16 L min^{-1} for intact GLP-1 and the metabolite, respectively [38].

Like GLP-1, the intact peptide GIP (1-42) is primarily inactivated through proteolytic cleavage by DPP-4, yielding the major metabolite GIP (3-42), and both the intact peptide and the metabolite are subject to renal elimination [39]. The half-life of GIP is considerably longer than that of GLP-1 and has been calculated as 5.0 ± 1.2 min for the intact peptide and 22.4 ± 3.0 min for the metabolite. The respective metabolic clearance rates were 3.18 ± 0.62 L min^{-1} and 1.56 ± 0.27 L min^{-1} [38].

Physiologic effects of incretin hormones

GLP-1

The GLP-1 receptor has been detected on numerous organs and tissues. High levels of GLP-1 receptors have been found on pancreatic β cells, δ cells, endothelial cells, cardiomyocytes, the gastrointestinal tract, and the kidneys [40]. The actions of GLP-1 have been summarized in Figure 11.3.

There is an ongoing debate as to the expression of GLP-1 receptors on pancreatic acinar cells and thyroid C-cells, with discrepant results being reported in different studies. Also, the expression of GLP-1 receptors of pancreatic α cells has been controversially discussed. Whereas most studies have failed to detect such receptors on α cells, others have reported small GLP-1 receptor numbers [40]. The discrepant results of different studies may be partly related to methodological problems with unequal specificities and binding characteristics of different commercially available GLP-1 receptor antibodies.

Modulation of islet hormone secretion

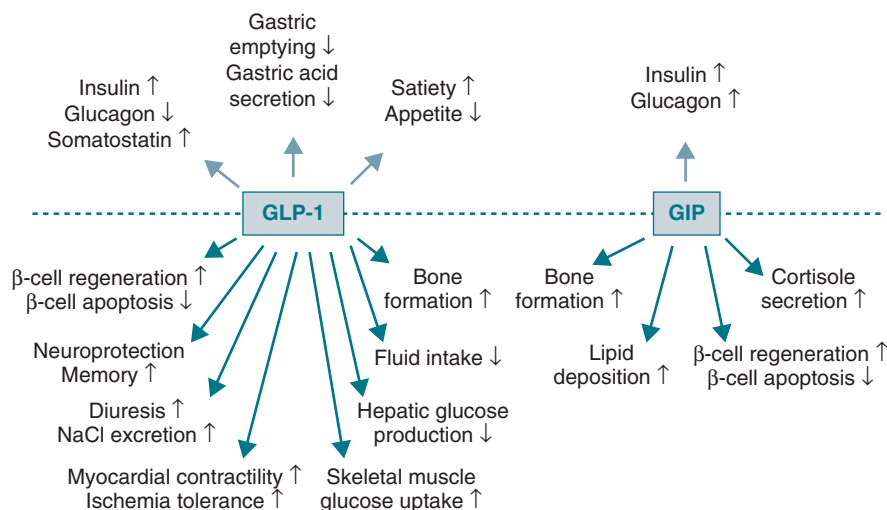
Intravenous administration of GLP-1 under fasting conditions leads to an immediate rise in insulin secretion [8,41]. These effects can be detected both at pharmacologic as well as physiologic plasma concentrations. In line with this, GLP-1 receptor knockout mice display significant reductions in insulin secretion [42]. Notably, GLP-1 stimulates insulin secretion only in the presence of hyperglycemia [43], and various experiments have demonstrated that the insulinotropic effect ceases once


Figure 11.3 More and less validated actions of GLP-1 and GIP. The upper half of the figure displays the major biologic effects of GLP-1 and GIP that have been well validated in human models. The lower half of the figure summarizes additional potential effects of the incretin hormones that have been described in various experimental models with only partial validation in physiologic human models.

normoglycemia has been reached [41]. Based on stepwise hypoglycemic clamp experiments, plasma glucose concentrations of more than $\sim$65 mg dL^{-1} will be necessary to allow for GLP-1 to augment insulin release [43].

The β-cell effects of GLP-1 have been show to be mediated through binding to the GLP-1 receptor on the cell surface [44]. Intracellular signaling involves generation of cAMP via protein kinase A [45]. This favors closure of ATP-dependent potassium channels, opening of voltage-gated calcium channels and exocytosis of insulin granules at elevated glucose concentrations [45]. Coupling of these processes to glucokinase action explains the glucose-dependency of the GLP-1 effects. However, GLP-1 alone cannot close ATP-dependent potassium channels and initiate insulin secretion at low glucose concentrations.

In addition to the direct insulinotropic effect, GLP-1 has also been demonstrated to enhance insulin biosynthesis [46]. Accordingly, islet insulin content was found to be increased after incubation with GLP-1 under culture conditions [47]. These properties may explain the durability of GLP-1 action on insulin secretion. Finally, experiments in isolated β cells have suggested that GLP-1 treatment confers glucose-competence to previously quiescent β cells [48]. This means that GLP-1 may recruit additional, previously inactive, β cells to the insulin secretory machinery. As a clinical correlate to these cell culture experiments, improvement of glucose-responsiveness in patients with diabetes has been demonstrated in "glucose ramp" experiments [49].

Suppression of glucagon concentrations is the second major islet cell effect of GLP-1 [8,41]. Similar to the insulinotropic effect, the suppression of glucagon levels by GLP-1 is strictly glucose-dependent, and hypoglycemic clamp experiments did not reveal any alterations of hypoglycemia counterregulation during GLP-1 infusion [43]. The effect of endogenous GLP-1 is also believed to be relevant for the physiologic control of glucagon secretion, since experiments with i.v. administration of the GLP-1 receptor antagonist exendin (9-39) have demonstrated a significant increase in glucagon concentrations after oral glucose ingestion [50]. There is some controversy as to the mechanisms underlying the suppression of glucagon secretion by GLP-1, since most studies did not detect sufficient amounts of GLP-1 receptors on pancreatic α cells. Inhibition of glucagon secretion secondary to the increase in insulin secretion cannot plausibly explain the effects either, because a similar reduction in glucagon levels has also been reported in patients with type 1 diabetes [51]. However, the finding that co-administration of a somatostatin receptor 5 antagonist abolishes the effects of GLP-1 on glucagon secretion in the isolated perfused pancreas suggests that the glucagonostatic effect of GLP-1 is secondarily mediated through an increase in somatostatin release from pancreatic δ cells [52].

Finally, reduction of PP secretion has been demonstrated in response to GLP-1 administration. This effect is held to be mediated via an inhibition of vagal nervous activation [53].

Gastrointestinal effects

Inhibition of gastric emptying during intravenous infusion of GLP-1 has been demonstrated using various techniques both in healthy individuals and in patients with type 2 diabetes [54–56]. Unlike the effects on islet cell secretion, the deceleration of gastric emptying by GLP-1 is rather independent of plasma glucose concentrations, but exhibits a clear dose-response relationship [56]. More specifically, a prolongation of the lag period along with a dose-dependent inhibition of antral propagations and antroduodenal contractions has been reported during GLP-1 administration.

The finding that administration of the GLP-1 receptor antagonist exendin (9-39) increases gastric antral motility and reduces pyloric tone suggests a role for endogenous GLP-1 in the physiologic control of gastric emptying. These actions are believed to contribute to the so-called "ileal brake", that is, the inhibition of gastric emptying by humoral and neural signals from the lower parts of the small intestine [57].

A transient reduction of exocrine pancreatic secretion has also been reported during GLP-1 administration [54]. However, it is difficult to judge whether these effects are due to a direct pancreatic effect of GLP-1 on the exocrine pancreas or rather secondary to the delay in gastric emptying leading to reduced secretion of gastrointestinal hormones that would in turn stimulate exocrine pancreatic secretion [58].

Furthermore, some earlier studies in humans have suggested a modest reduction in gastric acid secretion by intravenous GLP-1 infusion [59].

Mechanistically, the deceleration of gastric emptying by GLP-1 is believed to be mediated by an inhibition of vagal activation [53]. In support of this, co-administration of atropine in humans as well as afferent vagal denervation in rats have abolished the gastric effects of GLP-1 [60].

Because retardation of gastric emptying inevitably results in delayed and protracted glucose appearance in the systemic circulation, postprandial insulin concentrations are typically reduced during GLP-1 administration [55,56]. This observation has led to some controversy as to whether GLP-1 really fulfills the classical criteria of an incretin hormone (i.e., an augmentation of postprandial insulin secretion at typical plasma concentrations) [61]. The importance of the gastric emptying effect of GLP-1 also becomes apparent from experiments, in which the prokinetic drug erythromycin was co-administered along with GLP-1 in order to antagonize the deceleration of gastric emptying. Under those conditions, the GLP-1-induced reduction of postprandial glycemia was less pronounced than with GLP-1 alone, and the inhibition of insulin release was largely abolished [62].

Notably, the effect of GLP-1 on gastric motility appears to be subject to rapid tachyphylaxis and tends to wane with continued exposure to high GLP-1 plasma concentrations.

Central nervous effects

A role for GLP-1 in the central nervous regulation of food intake has been inferred from the high density of GLP-1 receptors in the hypothalamus [63]. Also, direct intracerebroventricular administration of GLP-1 has caused a significant reduction in food intake in rats, and these actions could be abolished by co-administration of the GLP-1 receptor antagonist exendin (9-39) [63]. These initial effects have been confirmed and extended by several other groups. Some studies have also reported a reduction of fluid intake by GLP-1 at pharmacologic concentrations [64]. Three potential sources of central nervous GLP-1 action have been suggested: (1) there is evidence for a local production of GLP-1 in the brainstem, from where the

peptide is believed to be transported along axonal networks into the CNS [65]; (2) studies in humans have demonstrated that peripherally produced GLP-1 can access the brain through certain areas that lack a typical blood–brain barrier, such as the *area postrema* and the subfornical organs [66]; (3) receptors on peripheral nerve ends in the gut mucosa, the portal venous bed as well as the vagal nerve are held to project to certain areas within the hypothalamus to exert action on appetite regulation and glucose metabolism [36].

In humans with and without diabetes, significant reductions of appetite sensations and food intake has been demonstrated during the exogenous administration of supraphysiologic amounts of GLP-1 [67]. These effects were found to be dose-dependent, and significant effects on food intake have only been observed with relatively high doses [68]. It is therefore questionable whether the endogenous secretion of GLP-1 plays a major role for the postprandial induction of satiety.

Other potential GLP-1 effects of unknown physiologic relevance

Aside from the well-characterized action on islet hormone secretion, gastrointestinal motility, and appetite regulation, a number of potential extra-glycemic actions of GLP-1 have been suggested. Evidence for these actions has been derived primarily from experimental studies in rodents or *in vitro* models. The physiologic significance of these actions is therefore largely unclear.

Regulation of islet cell death and turnover

Induction of β-cell proliferation during incubation with GLP-1 was first observed in β-cell lines as well as in isolated rodent islets [69]. Subsequently, these results have been confirmed in a large number of rodent studies, in which both islet neogenesis and replication of existing β cells have been described after treatment with GLP-1 or GLP-1 receptor agonists [70]. It has also been suggested that GLP-1 treatment promotes transdifferentiation of exocrine ductal cells into insulin-secreting β cells and induces expression of Pdx-1 in the pancreas [71,72]. The fact that GLP-1 receptor knockout mice exhibit abnormalities in islet cell architecture indicates some physiologic relevance of these effects for normal islet formation [73]. However, due to the inaccessibility of the human pancreas for biopsy sampling, it is as yet unclear whether GLP-1 also promotes β-cell proliferation in humans to a measurable extent. Furthermore, the vast majority of rodent studies demonstrating induction of β-cell proliferation with GLP-1 have been carried out in neonatal or infant rodent models, and more recent studies in adult mice and rats have called into question the stimulation of β-cell proliferation with GLP-1 receptor agonists, even at pharmacologic concentrations [74]. There is also evidence that the proliferative capacity of human β cells is much lower compared to rodent islets. In addition to β-cell proliferation, effects on β-cell apoptosis have also been ascribed to GLP-1. In isolated human islets, apoptosis was significantly reduced during incubation with the peptide [47],

and these effects have been reproduced in various animal and *in vitro* models [69,75]. Mechanistically, the reduction of β-cell apoptosis by GLP-1 is held to be mediated through a cAMP- and PI3K-dependent signaling pathway. The relevance of these preclinical findings for human physiology cannot be judged with certainty at present.

Cardiovascular effects of GLP-1

A potential cardioprotective role for GLP-1 has been initially suggested based on the indirect effects on various cardiovascular risk factors, such as glycemia, blood pressure, hyperlipidemia, and obesity [76]. Interestingly, whereas numerous studies have consistently demonstrated significant reductions in blood pressure during therapeutic administration of various GLP-1 receptor agonists [77], initial experiments in rodents had demonstrated the opposite effect of GLP-1 to even raise blood pressure [78]. GLP-1 receptors have also been identified directly on cardiomyocytes as well as on vascular smooth muscle cells [79]. A number of experimental studies have examined the effects of GLP-1 in ischemia-reperfusion models. Most of these studies have reported significant reductions in myocardial necrosis along with preserved contractility after exogenous administration of pharmacologic doses of GLP-1 or GLP-1 receptor agonists [80]. Furthermore, improved myocardial glucose uptake has been reported in dogs, and studies in experimental models of cardiomyopathy [81] or in humans with chronic heart failure have suggested a positive inotropic effect of GLP-1. There is also evidence for enhanced flow-mediated vasodilation after GLP-1 administration in humans. In rodent models of atherosclerosis, GLP-1 receptor activation has been shown to directly prevent the formation of atherosclerotic lesions [82]. Mechanistically, these cardioprotective properties of GLP-1 have been largely attributed to binding of GLP-1 to cardiac receptors with subsequent activation of intracellular PI3-kinase-dependent pathways [82]. More recently, the finding that cardioprotective GLP-1 effects were also observed in mice lacking a GLP-1 receptor as well as after administration of the GLP-1 metabolite (9-36) amine, which does not bind to the typical GLP-1 receptor, have led to speculation about a second GLP-1 receptor in the cardiovascular system [82]. However, as yet no such receptor has been identified. In recent clinical trials examining the effects of pharmacologic doses of GLP-1 receptor agonists, increases in heart rate of ∼3–6 beats per min were reported [82]. Overall, a large number of studies have demonstrated effects of GLP-1 in the cardiovascular system at supraphysiologic plasma concentrations. The importance of such effects in normal physiology is still largely unclear.

Neuroprotection

Mice with a GLP-1 receptor knockout are characterized by a learning deficit, which was found to be reversible after gene transfer of the GLP-1 receptor into the hippocampus, thereby suggesting a role for GLP-1 in learning processes [83]. Various rodent studies have also demonstrated that neuronal

cell damage can be partly prevented by the administration of GLP-1 or GLP-1 receptor agonists [83]. Finally, neuroprotective effects as well as enhanced neurogenesis have been reported in rodent models of Alzheimer's disease, Parkinson's disease, and Huntington's disease. The physiologic relevance of these preclinical findings is difficult to judge at present [84].

Other effects of GLP-1 that have been suggested include enhanced diuresis and renal excretion of sodium chloride, increased skeletal muscle glucose uptake and enhanced liver glycogen storage, and enhanced bone formation [84].

GIP

Similar to GLP-1, GIP acts through specific receptors belonging to the seven transmembrane-domain family of receptors. These receptors are expressed in the endocrine pancreas, on adipocytes, and in the brain [85]. The actions of GIP have been summarized in Figure 11.3.

Islet hormone secretion

Intravenous administration of porcine or human GIP has led to a dose-dependent stimulation of insulin secretion in humans. These effects were found to be glucose-dependent, with negligible insulinotropic activity at normoglycemia. The physiologic importance of these effects has become apparent from experiments with immunoneutralization of circulating GIP or in GIP receptor knockout mice. Both ways to eliminate GIP signaling have led to glucose intolerance in the respective experimental animals [85]. Also, when the GIP plasma concentrations that are typically measured after meal ingestion were mimicked by exogenous infusion in humans, a significant insulinotropic activity was recorded [86]. Studies in β-cell lines have also suggested anti-apoptotic properties as well as β-cell proliferative effects for GIP.

Whereas GIP shares the insulinotropic properties with the other major incretin hormone GLP-1, the effects of both incretins on glucagon secretion differ largely from each other. Thus, in normoglycemic healthy volunteers, GIP even exerts a dose-dependent stimulation of glucagon release [9]. These effects are no longer detectable under conditions of hyperglycemia or in patients with diabetes. When GIP and GLP-1 were co-administered to patients with type 2 diabetes, the glucagonostatic actions of GLP-1 were fully abolished, suggesting that under normal conditions, the stimulation of glucagon release by GLP-1 overrides the glucagonstatic effect of GLP-1 [10]. In line with this, suppression of glucagon levels was found to be significantly more pronounced after intravenous compared to oral glucose administration.

Gastrointestinal effects

When GIP was initially discovered, a prominent role of the peptide as an inhibitor of gastric acid secretion was inferred from experiments in isolated canine stomach preparations. These studies gave rise to the initial name "gastric inhibitory polypeptide," which was later replaced by the term "glucose-dependent

insulinotropic polypeptide" [85]. Indeed, when GIP was administered to humans with and without type 2 diabetes *in vivo*, no significant effect on gastric acid secretion was found [87]. Also, no effects of exogenous GIP on gastric emptying were reported. Therefore, the peptide does not seem to play a major physiologic role in the control of gastrointestinal functions in humans.

Regulation of body weight

A potential role for GIP as a regulator of body weight became apparent from experiments in GIP receptor knockout mice. These animals were protected from developing obesity and insulin resistance on a high-fat diet [88]. In line with these experiments, studies using various GIP receptor antagonists have demonstrated improvements in glucose homoeostasis and weight gain in mice. Unfortunately, these findings have not yet been confirmed in humans or large animal species. There is also good evidence that GIP receptors are expressed abundantly on adipocytes, where the incretin is believed to induce lipoprotein lipase activity and to promote triglyceride accumulation [85]. These effects were shown to be partly mediated through increased secretion of resistin. In contrast to these experiments in rodent and cell culture models, administration of GIP to humans has had no significant effect on triglyceride or free fatty acid levels.

Other potential actions of GIP

In addition to the above-mentioned effects, there is some evidence for a stimulation of cortisol secretion by GIP [89]. Furthermore, GIP is believed to enhance bone formation through stimulation of osteoblast activity as well as inhibition of osteoclast resorptive activity.

Other gastrointestinal hormones with potential incretin function

Whereas various lines of evidence suggest that GIP and GLP-1 are the major incretin hormones in human physiology, some incretin-like activity has also been ascribed to several other gastrointestinal hormones.

Cholecystokinin (CCK)

Earlier studies, partly using rather nonspecific immunoassays, have reported reduced plasma concentrations of CCK in patients with type 2 diabetes, thereby suggesting a role for the peptide in the pathogenesis of diabetes. Indeed, CCK has been demonstrated to exert glucose-dependent insulinotropic effects in various experimental models [90]. However, at physiologic plasma concentrations, these effects were rather negligible, thereby questioning a true incretin function of the peptide. Furthermore, there appears to be a large interspecies variability regarding the insulinotropic effect of CCK, and experiments in humans did not reveal a strong stimulation of insulin secretion [90]. More importantly, the incretin effect was largely preserved

after administration of the CCK receptor antagonist loxiglumide [91]. On that basis, even though CCK may exhibit some characteristics of an incretin hormone, it clearly cannot be considered a major physiologic mediator of the incretin effect [92].

Secretin

Secretin is another gut peptide with potential incretin-like properties that is secreted from gastrointestinal S cells, which are primarily located in the duodenum and upper jejunum. Secretion of secretin is stimulated by nutrient ingestion, with fat and protein acting as strong stimulators, and glucose being a rather weak stimulus. Stimulation of insulin secretion has been described in response to secretin administration in various species, but at physiologic plasma concentrations the insulinotropic effect of the peptide is rather weak, thereby questioning an incretin role of the peptide [16,92].

Gastrin

The hormone gastrin is secreted from G cells located in the gastric antrum and duodenum. Gastrin secretion rises modestly in response to oral glucose administration [92]. However, circulating plasma levels are also strongly affected by many other factors, such as gastric pH. Some, but not all studies have demonstrated a glucose-dependent stimulation of insulin release in response to gastrin administration. More recently, a role for gastrin in β-cell growth and regeneration has also been implicated. Overall, the magnitude of the insulinotropic effect observed with physiologic gastrin levels does not appear to be sufficient to elicit a true incretin-like activity [16,92].

The incretin effect in patients with diabetes

The "size" of the incretin effect, that is, the percentage contribution of incretin hormones at total insulin responses to oral glucose, has been estimated at ∼35–75%, depending on the magnitude of the glucose load [6]. In a direct comparison of the incretin effect after 50 g of oral glucose between patients with type 2 diabetes and nondiabetic controls, the size of the incretin effect was $72.8 \pm 6.9\%$ in control subjects and $36.0 \pm 8.8\%$ in diabetic patients based on insulin measurements and $58.4 \pm 7.6\%$ and $7.6 \pm 14.5\%$, respectively, based on C-peptide levels [93]. Because insulin concentrations are largely affected by hepatic insulin clearance, and oral glucose ingestion has been shown to reduce hepatic insulin clearance, it seems appropriate to primarily use C-peptide levels for the calculation of the incretin effect. On that basis it can be concluded that the incretin effect is almost completely absent in patients with type 2 diabetes. Given the importance of the incretin effect for the regulation of postprandial glucose homoeostasis, it has been speculated that a loss of the incretin effects may play a central role in the pathogenesis of type 2 diabetes [94].

The incretin effect has also been examined in patients with other types of diabetes. Interestingly, when GIP and GLP-1 were

administered intravenously to patients with diabetes secondary to chronic pancreatitis, patients with MODY, LADA or early type 1 diabetes, the insulinotropic actions of the incretin hormones was reduced to a comparable extent as in patients with type 2 diabetes. In line with these observations, the size of the incretin effect was also found to be largely reduced in such patients. Taken together, these studies have lent strong support to the concept that the reduction in the incretin effect in patients with type 2 diabetes develops secondary to chronic hyperglycemia and goes along with a general decline in β-cell mass and function in these individuals [94,95].

Potential mechanisms of incretin dysfunction in type 2 diabetes

Various potential explanations have been expounded in order to explain the reduced incretin effect in type 2 diabetes [11,95]. One obvious factor to examine was the secretion of GIP and GLP-1. Regarding GIP, a number of studies have compared postprandial plasma concentrations between patients with and without diabetes. These studies have revealed increased, normal, or reduced GIP levels in patients with diabetes. Considering all studies together, there does not appear to be a general defect in

GIP secretion [95] (Figure 11.4). If anything, a slight increase in postprandial GIP levels might occur in patients with early type 2 diabetes, but clearly the differences in GIP levels would not sufficiently explain any alterations in insulin of glucose concentrations [11].

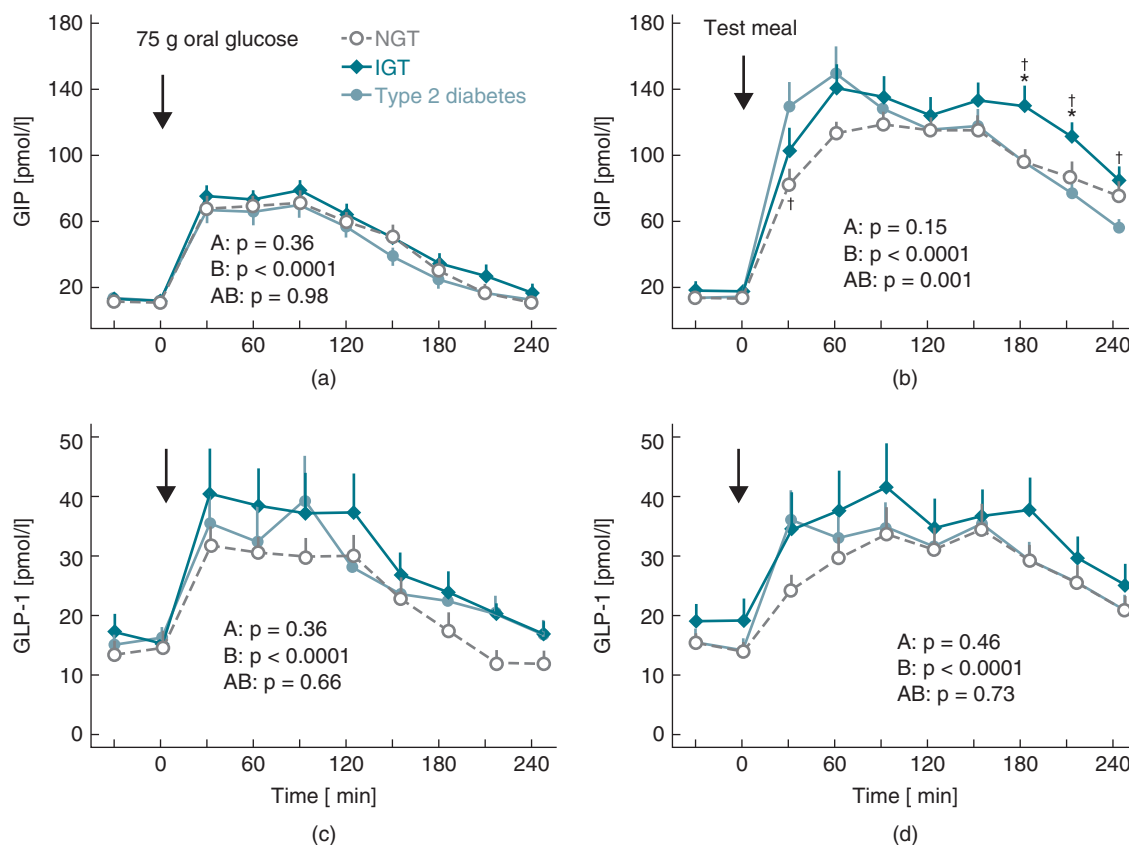
There is some controversy regarding GLP-1 concentrations in patients with type 2 diabetes. One large cross-sectional study has reported a modest reduction in postprandial GLP-1 concentrations in patients with type 2 diabetes compared to nondiabetic control subjects. In this study, there was also a small reduction in GLP-1 levels in individuals with impaired glucose tolerance [20]. However, upon closer analysis, the defects in GLP-1 secretion in type 2 diabetes found in this study were most apparent in the late postprandial period, that is, ~120–240 min after meal ingestion. Because defects in insulin secretion in type 2 diabetes typically occur within the first 30–60 min after meal or glucose ingestion, such defect in GLP-1 levels would not plausibly explain the reductions in postprandial insulin secretion. A reduction in GLP-1 levels in patients with type 2 diabetes has also been reported in another study [21]. In this study, reduced plasma concentrations of both total and intact GLP-1 were reported. These two studies reporting lower GLP-1 levels are contrasted by a number of other studies demonstrating normal or even increased GLP-1


Figure 11.4 Plasma concentrations of GIP and GLP-1 after oral glucose ingestion (A, C) and mixed meal ingestion (B, D) in patients with type 2 diabetes, individuals with impaired glucose tolerance (IGT) and healthy control subjects. Source: Vollmer 2008 [19].

concentrations in type 2 diabetes (Figure 11.4). In a formal meta-analysis of all these trials, there were no differences in GLP-1 concentrations between patients with and without type 2 diabetes [96]. The discrepant results of these studies may be partly explained by different patient characteristics. In this regard, long diabetes duration and high glucagon plasma concentrations have been associated with modest reduction in GLP-1 levels [96]. All aspects considered, a reduction in the secretion of GIP or GLP-1 does not explain the impaired incretin effect in type 2 diabetes.

The insulinotropic effect of the two major incretin hormones has been examined in a number of experiments (Figure 11.5). For GIP, a reduced insulinotropic effect in type 2 diabetes has already been reported in initial experiments using porcine GIP preparations [86]. In a hyperglycemic clamp study directly comparing the insulinotropic effect of GIP at physiologic and supraphysiologic doses in patients with type 2 diabetes, the efficacy of GIP was reduced by ∼ 60% in the diabetic patients [97] (Figure 11.5). This finding has been subsequently confirmed in different studies. Notably, the loss of insulinotropic activity of GIP could not be overcome even by the administration of highly supraphysiologic doses [11]. The efficacy of GIP was also found to be impaired to a lesser extent in first-degree relatives of patients with type 2 diabetes, along with a general reduction in β-cell function. The mechanistic reasons underlying the

loss of GIP efficacy in type 2 diabetes have not been fully elucidated [11]. Polymorphisms in the GIP receptor have recently been related to 2-h glucose concentrations during an OGTT in nondiabetic individuals. However, the effect size of this polymorphism is clearly insufficient to explain the marked abnormalities in GIP action in patients with type 2 diabetes. It has also been speculated that patients with type 2 diabetes may exhibit a reduced number of GIP receptors on pancreatic β cells, but until now, GIP receptor expression has not yet been quantified on islets from patients with type 2 diabetes. However, in rodents with diabetes a reduced expression of GIP receptors has been described, and the expression level of the GIP receptor was found to be modulated by the prevailing glucose concentrations. In line with these studies in rodent models, the insulinotropic action of the incretin hormones was found to be largely enhanced after reduction of chronic hyperglycemia by means of intensive insulin therapy in patients with type 2 diabetes. Therefore, at present the most plausible explanation for the loss of GIP efficacy in type 2 diabetes is a downregulation of GIP receptor expression secondary to chronic hyperglycemia [11].

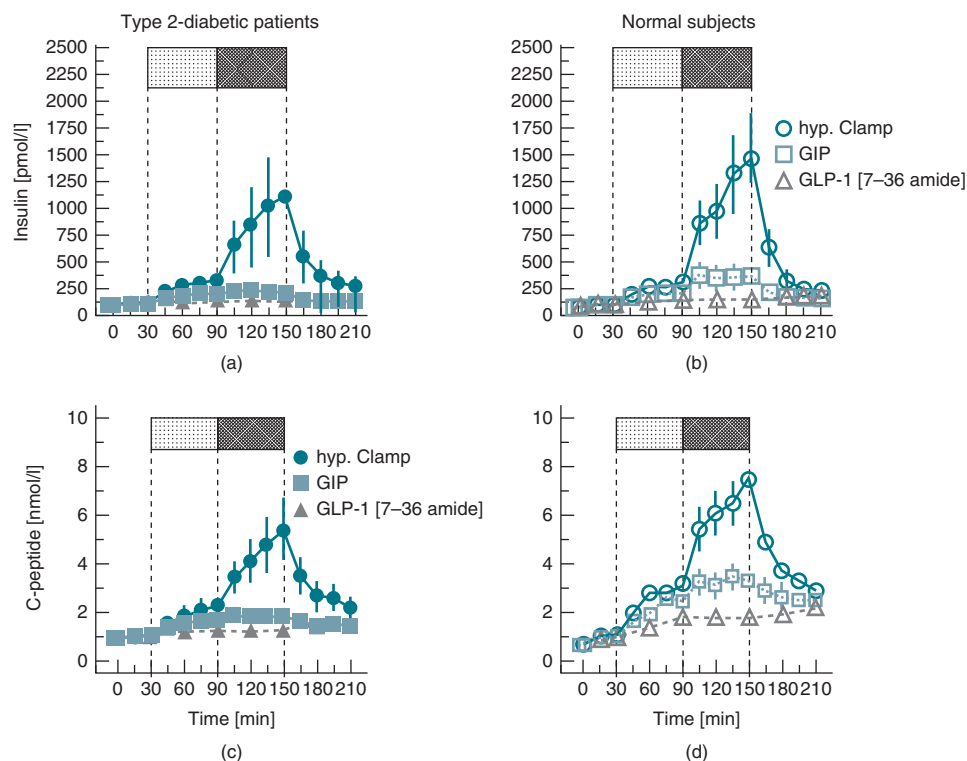
When directly compared to nondiabetic individuals, the insulinotropic effect of GLP-1 has also been found to be reduced in patients with type 2 diabetes [97]. However, the extent of this defect is clearly less pronounced than the respective impairment


Figure 11.5 Immunoreactive insulin (upper panels) and C-peptide (lower panels) during hyperglycemic clamp experiments with and without the infusion of synthetic human GIP or GLP-1 (7-36) amide in type 2 diabetic patients (left panels) and normal subject (right panels). Mean ± SEM. The dotted lines separate periods of low (▱) and high (▨) dose administration of GIP or GLP-1 (7-36) amide. Source: Vollmer 2008 [19].

in GIP action. Thus, in a hyperglycemic clamp study examining individuals with and without type 2 diabetes, the insulinotropic effect of GLP-1 was reduced by ~30% in the diabetic patients [97]. Of note, this impairment in GLP-1 action appears to be less than what would be expected in such patients, assuming a ~50–65% β cell deficit in type 2 diabetes [11]. Moreover, the impairment in GLP-1 action can easily be overcome by administration of supraphysiologic doses. Thus, even though in absolute terms the insulinotropic effect of GLP-1 is reduced in type 2 diabetes, this incretin hormone still appears to stimulate insulin secretion to a much greater extent than GIP or other secretagogues. The largely preserved insulinotropic activity of GLP-1 in patients with type 2 diabetes may be secondary to the recruitment of additional β cells, as demonstrated in a series of elegant experiments in isolated β cells [48].

Although the impairment in incretin activity in type 2 diabetes primarily affects their insulinotropic effect, it is still conceivable that the actions of GIP or GLP-1 on glucagon secretion may also be affected. However, in a direct comparison between patients with and without type 2 diabetes, the glucagonostatic effect of GLP-1 was fully preserved [97]. In this regard it is worth mentioning that GLP-1 has been found to normalize glucagon levels even in patients with type 1 diabetes [51]. For GIP, a glucagonotropic effect has been described in healthy individuals at normoglycemia [9]. These effects were no longer detectable at hyperglycemia or in patients with type 2 diabetes. Therefore, alterations in glucagon secretion do not seem to contribute to the loss of incretin activity in type 2 diabetes.

An alternative explanation to the concept of GIP receptor downregulation as a mechanism for the loss of incretin activity in type 2 diabetes would be a general decline in β-cell mass and function in these patients [11]. According to this hypothesis, the reduction in GIP activity in type 2 diabetes largely goes along with a general decline in β-cell function. Indeed, the insulinotropic effect of GIP is closely correlated to the insulin responses after intravenous glucose administration. Also, a gradual decline insulin secretion with chronic hyperglycemia has been described for both glucose-stimulated and GIP-induced insulin secretion. It is also worth considering the fact that the isoglycemic clamp design may lead to an underestimation of the incretin effect in individuals with a general reduction in their functional β-cell capacity [11]. Thus, because oral glucose represents a relatively large β-cell stimulus (which comprises the actions of 50 g or absorbed glucose plus the insulinotropic effects of GIP and GLP-1), whereas the β-cell stimulation by an isoglycemic i.v. glucose infusion is relatively weak (~20–25 g of glucose only), it is likely that in individuals with a general impairment in β-cell function the insulin response to the oral glucose stimulus is reduced to a greater extent than the response to the i.v. glucose infusion. On that basis, one would plausibly expect that the incretin effect, that is, the difference in insulin responses between oral and i.v. glucose, diminishes with declining β-cell mass. In line with such argumentation, an inverse relationship between fasting

glucose concentrations and the size of the incretin effect has been described. Thus, even though the insulinotropic effect of the incretin hormones, especially GIP, is clearly diminished in patients with type 2 diabetes, it is likely that the degree of impairment of the incretin effect is overestimated because of the experimental conditions [11].

Summary and conclusions

The incretin hormones GIP and GLP- play a predominant role in the postprandial augmentation of insulin secretion, thereby largely contributing to the maintenance of glucose homeostasis after meal ingestion. Incretin-like properties have also been ascribed to other gut hormones, such as CCK or secretion, but the importance of these other peptides is rather negligible under physiologic conditions. In addition to their insulinotropic effects, GIP and GLP-1 exhibit numerous other actions in various other organs and tissues, such as the central nervous system, the gastrointestinal tract, and the cardiovascular system. In patients with diabetes, the incretin system is markedly altered, which appears to be primarily due to loss of insulinotropic activity of GIP. Therefore, the incretin system represents a central regulatory element in the interplay between nutrient absorption and glucose homeostasis, which is of critical importance for the physiologic control of energy homeostasis.

Key points

- The insulin signal is transduced as a web of interacting signal molecule cascades and effector systems. The final biologic action represents the net synergism of the combined facilitative, inhibitory, and complementary signaling pathways that interact with terminal functional systems.

- Insulin signaling begins with tyrosine phosphorylation of the insulin receptor and insulin receptor substrate molecules; however, signaling can be inhibited by serine phosphorylation of these same molecules mediated by inflammatory pathways.

- There are three major steps in signal transduction that facilitate divergence of activated pathways impacting multiple cellular functions and adding a high degree of regulatory flexibility: insulin receptor/receptor substrate docking molecules, PI-3 kinase, and Akt/protein kinase B.

- Insulin-mediated translocation of GLUT4 glucose transporters to the plasma membrane is a complex process involving parallel signal transduction pathways (insulin receptor/IRS/PI-3 kinase and CAP/Cbl/TC10), regulated exocytotic and retroendocytotic trafficking pathways for GLUT4-containing vesicles, and the cytoskeleton.

- Many insulin actions are mediated by effects on gene transcription due to factors that are either directly modified via insulin signaling mechanisms or indirectly via effects on glucose or lipid substrate metabolism.

- There are two major loci of defects contributing to human insulin resistance: impaired proximal signal transduction characterized by reduced tyrosine phosphorylation of insulin receptor and insulin receptor substrate molecules, and abnormalities in GLUT4 vesicle trafficking that impair translocation to the cell surface.

Introduction

Fuel homeostasis

The peptide hormone insulin is secreted from pancreatic β cells, and exerts a broad spectrum of anabolic effects in multiple tissues. In response to a meal, insulin stimulates uptake and storage of carbohydrate, fat, and amino acids, while, at the same time, antagonizing the catabolism of these fuel reserves. During periods of fasting, a fall in circulating insulin combined with increased secretion of counterregulatory hormones leads to breakdown of stored fuels and increased availability of metabolic substrates for cellular energy. In particular, insulin plays a key role in maintaining blood glucose level within a narrowly defined range despite large fluctuations in food intake. After a meal, insulin returns the organism to postabsorptive homeostasis by promoting uptake and storage of glucose as glycogen in skeletal muscle and liver, and by inhibiting hepatic glucose production via decrements in glycogenolysis and gluconeogenesis. Insulin also promotes triglyceride storage by suppressing fatty acid oxidation, increasing lipid synthesis in liver and adipose tissues, and via an antilipolytic effect in fat cells. Insulin's actions extend to protein accretion through a diminution in protein catabolism and an increase in translation, to cell growth and differentiation, and to cell survival as a consequence of mitogenicity and anti-apoptosis.

Changing perspectives of insulin action

In mediating its pleiotropic actions, insulin engages multiple networks of signal transduction molecules and a wide array of effector systems. Insulin alters activity of enzymatic pathways, subcellular localization of enzymes, and activation state of membrane transport systems by regulating the posttranslational modification, translation, and degradation of proteins in cells and by affecting gene transcription and expression. The classical approach to the review of insulin action is to describe a linear cascade of sequentially-interacting signal transduction molecules, which then engage specific effector systems, such as membrane transport proteins or the activities of rate-limiting enzymes (e.g. glycogen synthase). This narrow perspective is myopic for three reasons. First, signal

transduction and effector functions are not clearly distinct. For example, phosphatidylinositide-3 kinase (PI-3 kinase), which is a component of linear signal transduction from insulin receptor to activation of Akt/protein kinase B (Akt/PKB) and protein kinase C (PKC) isoforms, is integrally involved in glucose transport system effector functions such as vesicle trafficking and the actin cytoskeleton [1].

Secondly, it has become clear, partly through the study of genetic disruption and hyperexpression in mice, that insulin activates numerous systems of signal transduction. These systems are at least partially redundant and are able to interact in modulating signal transduction and ultimate biologic effects. One example is the ability of Akt/PKB, activated through the PI-3 kinase "metabolic" signaling pathway, to impact mitogenic responses through regulation of gene transcription factors. Furthermore, signal transduction systems and effector systems must work in concert to mediate a given biologic effect. For example, stimulation of glucose transport requires parallel activation of PI-3 kinase and CAP/Cbl/TC10 signal pathways, as well as interaction between two effector systems, the glucose transport system (i.e., trafficking of GLUT4-containing vesicles) and effects on the cellular cytoskeleton. Thus, promulgation of insulin action is most accurately viewed as a changing pattern of network interactions involving a web of signal molecule cascades and effector systems. The final biologic action represents the net synergism of the combined facilitative, inhibitory, and complementary signaling pathways that interact with more terminal functional systems in cell biology. Certain aspects of linear insulin signal transduction are evolutionarily conserved and are quite similar in mammals and invertebrates. However, complex patterns of interactions between signal and effector systems are more pronounced in mammals and allow for greater plasticity in adaptive responses.

Thirdly, the classic descriptions of insulin signaling pathways emphasize insulin action mechanisms within certain target cells, especially fat cells. However, these actions at the level of cells and tissues affect substrate flux and release of hormones and tissue factors resulting in the coordinated function of multiple organs as whole organisms adapt to the nutritional environment. The reader is encouraged to think about insulin action in the context of systems biology and integrative physiology. This chapter will emphasize insulin action involving stimulation of glucose transport and glucose metabolism, for reasons outlined later. However, this information will complement other chapters depicting insulin's ability to regulate protein metabolism (Chapter 16), fat metabolism (Chapter 17), and intermediary metabolism (Chapter 13).

Insulin resistance

Interest in defining molecular mechanisms mediating insulin action has accelerated with the recognition that insulin resistance is both a primary abnormality in the evolution of type 2 diabetes (T2DM) and is also associated with a cluster of risk factors predisposing to cardiovascular disease (the metabolic syndrome) [2]. The cardinal clinical manifestations of insulin resistance include hyperinsulinemia in conjunction with normoglycemia or hyperglycemia. Investigators have used various *in vivo* metabolic techniques that assess glucose uptake during insulin infusions to demonstrate that insulin resistance was due to impaired insulin action in peripheral tissues. These conclusions were subsequently confirmed with the demonstration that insulin-stimulated glucose transport was diminished in fat and muscle tissues removed from insulin-resistant subjects and studied *ex vivo*. Therefore, while insulin resistance could apply to any of insulin's pleiotropic effects, the term generally applies to insulin's ability to stimulate tissue glucose uptake and suppress hepatic glucose production since these actions are most directly relevant to its clinical manifestations (hyperinsulinemia and impaired glucose tolerance). This chapter will primarily focus on mechanisms of insulin action related to the regulation of glucose transport and metabolism. While many key aspects remain to be elucidated, this field is rapidly advancing. Over the past decade, the application of new and improved methodologies in molecular biology have facilitated the study of insulin action, resulting in new knowledge and new ways to conceptualize the effects of this powerful and interesting hormone.

Insulin receptors

Ligand binding

The insulin action sequence is initiated with specific binding to high-affinity receptors on the plasma membrane of target cells. The insulin receptor is a large transmembrane glycoprotein consisting of two α- and two β- subunits that form a heterotetramer, as depicted in Figure 12.1. The insulin receptor is synthesized from a single gene as a polypeptide proreceptor comprised of α- and β- subunit sequences in tandem. The proreceptor is processed into separate α- and β- subunits which then assemble as a disulfide-linked holoenzyme of stoichiometry $(\alpha\beta)_2$ [3]. The 135 kDa α subunits, derived from the amino-terminal portion of the proreceptor, reside entirely on the outside of the cell, tethered to the membrane via the 95 kDa β subunits which span the membrane. Insulin binds to the extracellular α subunit. Studies using chimeric receptors containing structural domains from the homologous insulin-like growth factor-1 (IGF-1) receptor have established that multiple extracellular regions including glycine-centered repeats in the α subunit establish the specificity for insulin binding [4]; however, a cysteine-rich domain has been shown to directly interact with the ligand. Insulin binding results in conformational changes that bring the α subunits closer together, and enables ATP to bind to the intracellular domain of the β subunit.

Tyrosine kinase activity

The β subunits possess tyrosine kinase activity [5,6]. The initial event following insulin-binding appears to be phosphorylation
Figure 12.1 Structural and functional domains of the insulin receptor. Schematic diagram of the insulin receptor showing structural landmarks (left side) and functional domains (right side). (Numbering of amino acids based on translation of the alternatively spliced exon 11.) (For a color version of this figure, please see color plate section.)

of one β subunit catalyzed by a specific domain in the other β subunit within the same heterotetramer, a reaction that has been termed "transphosphorylation" or autophosphorylation [7]. Autophosphorylation of the kinase renders it considerably more active, allowing the accelerated transfer of phosphate to other tyrosine sites within the same receptor as well as exogenous substrates [8]. Ligand-dependent stimulation of the β-subunit tyrosine kinase activity is critical for promulgation of the insulin signal. There is an ATP-binding domain in the β subunit, and at least six tyrosine residues undergoing phosphorylation that have been shown in mutagenesis experiments to serve different roles in insulin signaling, as shown in Figure 12.1. These phosphotyrosines lie within three functional groups. Tyrosine phosphorylation sites at positions Y^{1158}, Y^{1162}, and Y^{1163} are essential for mediating an increase in subunit tyrosine kinase activity and signal transduction, and lie in the active loop of the kinase catalytic domain. When phosphorylated, a juxtamembrane tyrosine at position Y^{972} becomes part of a recognition motif and provides a docking site for several intracellular substrates. Y^{972} is required to assure sufficient stability of the receptor/substrate complex for substrate phosphorylation. Y^{972} also lies within a domain that mediates endocytosis of ligand-bound insulin receptors. Phosphorylation sites Y^{1328} and Y^{1334} near the COOH terminus are not essential for stimulation of glucose transport but may affect the sensitivity of Ras/MAP kinase pathway activation, and, so, are involved in the receptor's mitogenic responses [9]. Phosphorylation of serine and threonine residues within the insulin receptor

also occurs following insulin binding, and, as described later, phosphorylation of these residues by intracellular serine kinases can diminish receptor tyrosine kinase activity; it represents a regulatory feedback mechanism [10] and can induce insulin resistance under pathophysiologic conditions.

Insulin-like growth factors

The insulin receptor is similar in structure to IGF-1 and other growth factor and cytokine receptors (all $(\alpha\beta)_2$ stoichiometry), and IGF-II receptors $((\alpha\beta)$ stoichiometry), in having an extracellular ligand-binding domain that activates an intracellular tyrosine kinase domain [2,3,11]. The respective ligands, insulin and IGF-1, are also closely related hormones from an evolutionary perspective, but have widely different functions in regulating metabolism and growth, respectively. Nevertheless, it has been recognized for some time that these hormones can elicit similar effects to one another, if they are present at high concentrations. This suggested that they could bind to one another's receptors, with differing affinities. In fact, both IGF-1 and IGF-II can bind to cell surface insulin receptors. The affinity of IGF-1 for the insulin receptor is 100- to 1000-fold less than that for insulin. Nevertheless, circulating IGF-I concentrations can be 100-fold higher than insulin, such that there is some potential for IGF-I binding and action through the insulin receptor. IGF-II binds insulin receptors during embryogenesis in rodents, and promotes fetal growth. This capability may be associated with expression of an alternatively spliced form of the insulin receptor with high affinity for IGF-II [12]. Alternative

splicing in exon 11 determines the insertion or deletion of 12 amino acids near the COOH terminus of the α subunit. Isoform A lacking the 12 amino acids has high affinity for IGF-II, predominates during fetal development, and promotes growth as a consequence of IGF-II binding. Isoform B containing the 12 amino acids predominates postnatally and is activated mainly by insulin. Some evidence supports the contention that dysregulated expression towards the fetal pattern could occur in adult tissues and result in insulin resistance [12,13].

Hybrid receptors

Because of the heterotetrameric nature of the insulin and IGF-1 receptors, it was natural to ask whether individual dimers could be formed from "hybrid" receptors, consisting of one α/β insulin receptor dimer and one α/β IGF-1 receptor dimer. Such hybrid receptors were indeed demonstrated to exist [14–16], and it appears likely that these hybrid receptors form stochastically, such that if half of the dimers present were insulin receptor dimers, and half were IGF-1 receptor dimers, half of the mature receptors present in the membrane would be hybrid insulin/IGF-1 receptors, with about one quarter each "pure" insulin or IGF-1 heterotetramers. This raises the question of what the main ligand is for such hybrid receptors, and what downstream effects would be triggered when the hybrid receptors are occupied. Most evidence would suggest that hybrid receptors bind IGF-1 with greater affinity than insulin and mediate IGF-1-like effects [17].

The implication of these findings is that the ratio of IGF-1 to insulin receptor dimer subunits could have an important influence on the number of insulin receptor heterotetramers that exist in the plasma membrane and can actually function to mediate insulin's metabolic effects. Increased IGF-1 receptor expression can produce insulin resistance via increasing the proportion of hybrid receptors, essentially hijacking insulin receptor dimers to serve a function in IGF-1 signaling [16]. For example, aldosterone can induce vascular insulin resistance by this mechanism [18], and IGF-1 receptor expression can modulate insulin sensitivity and nitric oxide availability in endothelium [19]. Hybrid insulin/IGF-1 receptors may also play a role as growth factor receptors in myeloma cells [20] and endometrial cancer cells [21], as well as affecting the function of platelets [22]. The role of hybrid insulin/IGF-1 receptors in regulating insulin action and disease processes is an understudied area.

Insulin receptor mutations

Identification of functional domains within the insulin receptor has been accomplished by studying site-directed mutations, knockout and transgenic mice, and rare native mutations of the insulin receptor in patients with severe forms of insulin resistance. Native insulin receptor gene mutations have been detected in all major structural and functional domains, and generally either diminish ligand binding and/or impair β-subunit tyrosine kinase activity [23]. Five major categories

of insulin receptor mutations have been delineated that cause severe defects in insulin binding. These include: (i) nonsense or frameshift mutations that lead to premature termination of translation and decreased receptor synthesis; (ii) mutations that impair intracellular transport and posttranslational processing of receptors such that fewer receptors reach the cell surface; (iii) mutations in the insulin-binding domain that affect ligand affinity; (iv) mutations that enhance ligand-mediated endocytosis and degradation of insulin receptors; and (v) mutations that cause defects in receptor kinase activity. These latter mutations usually consist of point mutations in one of three areas within the β subunit: the ATP binding site, the tyrosine kinase domain, or other areas in the intracellular domain. Phenotypically, patients with syndromes of severe insulin resistance can exhibit mild diabetes or glucose intolerance with marked hyperinsulinemia, acanthosis nigricans, hyperandrogenism, and abnormalities of growth and development with precocious pseudopuberty and cardiac enlargement. Related disease categories include type A severe insulin resistance, lipoatrophic diabetes, leprechaunism, and Rabson–Mendenhall syndrome [24,25].

Insulin receptor substrate molecules

Receptor substrate/docking proteins

Following insulin binding and receptor autophosphorylation, the next committed step in signal transduction is tyrosine phosphorylation of intracellular proteins. To accomplish this, autophosphorylation of the β subunit mediates noncovalent but stable interactions between the receptor and intracellular substrate proteins, and this positions these molecules for tyrosine phosphorylation by the activated insulin receptor kinase [26–28]. Several proteins are rapidly phosphorylated on tyrosine residues by ligand-bound insulin receptors, including six insulin receptor substrate proteins (IRS-1, IRS-2, IRS-3, IRS-4, IRS-5, IRS-6) [29–33], Src-homology-collagen proteins (SHC) [34] and, growth factor receptor bound-2 (Grb-2) associated binder-1 (Gab-1) [35], signal-regulatory protein (SIRP) family members [36,37], the CAP/c-Cbl complex [38,39], an adapter protein with a PH and SH2 domain (APS) [40], signal transducer and activator of transcription 5B (STAT5B) [41], and proteins referred to as downstream of kinase (DOK 1-6) [33,42].

There is no known enzymatic activity associated with insulin receptor substrate molecules; however, their primary structure is noteworthy for multiple sites capable of interaction with other proteins. The receptor substrates are characterized by a representative architecture, particularly with respect to three functional domains. These include an N-terminal pleckstrin homology (PH) domain, an intermediate phosphotyrosine binding (PTB) domain, and a carboxy-terminal region of variable length that contains the multiple tyrosine and serine phosphorylation sites [26–28]. The PH domain helps position the insulin receptor for coupling with IRS, possibly

by binding to charged headgroups of certain phosphatidylinositides in adjacent membrane structures. PTB domains recognize the phosphotyrosine in an amino acid sequence asparagine-proline-any amino acid-phosphotyrosine (NPXpY), and this motif is present in the insulin receptor and other receptors with tyrosine kinase activity such as the IGF-1 receptor. In this manner, the PTB domain enables receptor substrates to directly bind Y^{972} of the insulin receptor β subunit. All of the receptor substrate molecules have PH domains except SHC, and all have a PTB domain except Gab-1. These domains facilitate binding of the receptor substrates to the phosphorylated insulin receptor, allowing for phosphorylation of tyrosine residues in their COOH-terminal domains.

In the carboxy end of insulin receptor substrate molecules, the phosphotyrosines provide binding sites (pYMXM) for other proteins containing Src homology-2 (SH2) domains. This term relates to homology with $pp60^{v-src}$, the sarc oncogene product and first protein kinase demonstrated to possess activity towards tyrosine residues [43]. Noncovalent attachment of SH2-containing signaling molecules allows receptor substrates to function as docking proteins that appose proteins in the transduction cascade. Receptor substrates thus propagate the insulin signal via the docking, apposition, interaction, and activation of downstream signal molecules, rather than as a consequence of any intrinsic enzymatic activity. This system provides for extensive plasticity and regulation. For example, the multiple receptor substrate molecules exhibit differences in tissue-specific expression and in their capacity to activate various downstream signal pathways. In addition, the receptor substrates can be acted upon by multiple receptor tyrosine kinases, such as IGF-1, interleukin, and integrin receptors, as well as serine kinases (see later), in a manner that allows for modulation of insulin signal and integration of responses to extracellular factors. Thus, these docking molecules provide for divergence, heterogeneity, and regulation of insulin signal transduction processes.

Insulin receptor substrate (IRS) family of docking proteins

IRS-1 and IRS-2 exhibit a wide range of tissue expression, including muscle, fat, liver, and pancreatic islets, although their relative levels can vary in different tissues [27–30]. IRS-3 is expressed in adipose tissue, fibroblasts, and liver cells, while IRS-4 has been detected in brain, thymus, and embryonic kidney [31,32]. IRS-5 is ubiquitously expressed but most abundant in kidney and liver. IRS-6 expression is highest in skeletal muscle [33]. Knockout mouse models have highlighted functional differences among the IRS protein family. Genetic ablation of IRS-1 leads to severe growth retardation reflecting a decrease in growth-promoting effects of insulin and other factors which signal through IRS-1 [44,45]. These mice were also insulin resistant but did not develop overt diabetes. On the other hand, ablation of IRS-2 produced insulin resistance, impaired insulin secretion, and overt diabetes in mice that were

normal in size [46]. The IRS-2 knockout mice were observed to have decreased β-cell mass and insulin content, indicative of a trophic role for insulin signaling through IRS-2 in β-cell development. Genetic ablation of IRS-2 recapitulates the pathogenesis of T2DM in that diabetes arises only when insulin resistance and insulin secretion are both impaired in these knockout mouse models. IRS-3 knockout mice do not have an obvious phenotype, and IRS-3 has not been detected in the human genome. IRS-4 null mice also appear normal with the exception of reduced fertility. While IRS-5 and IRS-6 undergo insulin-stimulated tyrosine phosphorylation, their relevance to insulin action has been questioned, as both isoforms show very weak affinity for the insulin receptor [47]. Therefore, IRS-1 and IRS-2 are the IRS isoforms most critically important in glucose homeostasis. The consensus that has arisen from these studies is that, while the IRS family members to some extent represent duplicative pathways for insulin signal transduction, IRS-1 functions as the principal IRS in skeletal muscle, and that IRS-2 predominates in liver and β cells where insulin action is required for normal β-cell growth and development.

In addition to PH and PTB domains assuring close apposition to the insulin receptor, IRS-2 (but not other IRSs) contains another region that interacts with the phosphorylated regulatory loop of the insulin receptor kinase, and this region has been designated the kinase regulatory loop binding domain (KRLB) [41,48,49]. Crystal structure analysis of a portion of the KRLB domain indicates that this region acts to restrict tyrosine phosphorylation of IRS-2 [50]. While the KRLB domain could confer some measure of signal specificity, it is unclear whether the presence of the KRLB explains the differences in phenotype between IRS-1 versus IRS-2 knockout mice.

IRS proteins are a key locus for regulation of insulin action. One mechanism occurs at the level of IRS protein expression; for example, IRS-1 and IRS-2 proteins are decreased by hyperinsulinemia [51]. Cell loss of IRS could occur through accelerated protein degradation due to induction of ubiquitin-mediated degradation of IRS-1 and IRS-2 by SOCS proteins [52], or by inhibition of IRS gene transcription. Regardless of the mechanism, decreased levels of IRS proteins in hyperinsulinemic states, coupled with downregulation of the insulin receptor itself, can contribute to the insulin resistance in diabetes [53]. The function of IRS proteins can also be negatively regulated by serine/threonine kinases and protein tyrosine phosphatases such as PTP1B and SHP2 [54] as described later. In addition, IRS-1 can be posttranslationally modified by either by O-linked N-acetylglucosamine adducts (O-GlcNAc) on serine/threonine residues under hyperglycemic conditions [55], or by S-nitrosylation as a consequence of nitric oxide generation [56]. These modifications induce the proteasomal degradation of IRS-1 and insulin resistance [57].

Other receptor substrates

Like IRSs, SHC proteins are phosphorylated in response to insulin, lack any known catalytic activity, and interact with

SH-2 domain-containing proteins through their tyrosine phosphorylation sites [34]. A phosphorylation site on SHC binds Grb-2, which can then lead to the activation of the Ras/MAP kinase mitogenic signaling pathway. Therefore, SHC constitutes an additional substrate for the insulin receptor kinase and transduces the insulin signal via its protein docking properties. There are at least three known SHC isoforms (46, 52, and 66 kDa), and all contain an amino terminal phosphotyrosine-binding domain, a central region that is homologous to the α1 chain of collagen, and a carboxy terminal SH-2 domain.

Gab-1 contains only a PH domain at the amino terminus and a domain containing several tyrosine phosphorylation sites, but lacks a PTB domain [35]. In this case, the PH is sufficient for positioning Gab-1 adjacent to the insulin reptor and enabling phosphorylation, although a tight anchor is not possible due to the lack of a PTB domain. Gab-1 is most heavily phosphorylated by the ligand-activated epidermal growth factor receptors, another receptor containing tyrosine kinase activity, and less well by activated insulin receptors.

The DOK family consists of DOK1 through 7 and are similar to IRS family members in domain architecture [33,42,58]. DOK proteins appear to have functional effects in lymphocytes, myeloid cells, muscle cells, and neurons, and can be phosphorylated by both membrane-associated and cytoplasmic tyrosine kinases. DOKs are docking proteins that have been observed to associate with Ras GTPase-activating protein (RasGAP), Nck, c-Abl, and the insulin receptor, and in cultured cells can be involved in cytoskeletal reorganization. DOK1 (p62dok) has been shown to negatively regulate insulin-stimulated activation of AKT [59], although the role of the remainder of the DOK family proteins in mediating the biologic effects of insulin is not well understood.

Proteins that dock with receptor substrate molecules

SH2-containing proteins, which bind to phosphotyrosine motifs and dock with insulin receptor substrate proteins, include proteins with enzymatic activity such as PI-3 kinase, Fyn (tyrosine kinase), Csk (tyrosine kinase), and SHIP-2 (phosphotyrosine phosphatase), and other adapter proteins such as Grb-2, Crk, APS, and Nck [27,28]. In addition to SH2 domains, the adapter proteins also contain SH3 domains, which bind to proline-rich sequences in other proteins with consensus sequence PXXP. In this way, the adapter proteins associate with receptor substrates via their SH2 domains and bring with them other proteins bound to their SH3 domains. The SH3-bound proteins represent downstream signaling molecules and catalytic subunits, which participate in transduction of the insulin signal. The proteins that dock with receptor substrates, whether binding directly or via adapters, have different enzymatic activities that activate specific downstream molecules as a result of their juxtaposition on receptor substrate docking molecules. In this way, insulin

receptor substrates provide the first major point of divergence of insulin signal transduction pathways, leading to activation of the mitogenic (Ras/MAP kinase), and metabolic (PI-3 kinase) pathways. This is illustrated in Figure 12.2.

Ras/MAP kinase pathway: mitogenic signaling

One component of signal divergence emanating from IRS docking proteins is the engagement of the Ras/MAP kinase mitogenic signaling pathway (Figure 12.2). One of the SH-2 domain-containing proteins that docks with IRS is Grb-2, a small cytosolic adapter protein. Grb-2 also contains an SH-3 binding domain which binds proteins via interaction with proline-rich sequences, and one of these proteins is SOS (mammalian homologue of the Drosophila son-of-sevenless protein), a GDP/GTP exchange factor. Following insulin stimulation, Grb-2 is able to bind IRS via its SH-2 domain, and position SOS for activation of the Ras signaling pathway. SOS facilitates GTP activation of membrane-bound Ras, the 21 kDa small molecular weight GTPase, which has been demonstrated to play a major role in cell growth and oncogenesis. The GTP-bound form of Ras complexes with and activates Raf-1 kinase, and initiates a cascade leading to sequential phosphorylation and activation of MAP kinase kinase, MAP kinase, and p90[RSK]. Insulin receptors can also mediate activation of the Ras/MAP kinase pathway through another substrate docking molecule, SHC [60]. Similar to IRSs, SHC activates Ras and the MAP kinase pathway by forming a complex with Grb-2/SOS in response to insulin. Whether activated through IRS or SHC, MAP kinase translocates into the nucleus where it phosphorylates transcription factors mediating the mitogenic and growth promoting effects of insulin [61]. Phosphorylation of nuclear transcription factors modulates their DNA binding properties and ability to regulate gene transcription. For example, p90[RSK] phosphorylates c-fos, and MAP kinase phosphorylates Elk-1, increasing transcriptional factor activity in both instances. The MAP kinase cascade is also one of the pathways with the potential to stimulate glycogen synthase since p90 S6 kinase is able to activate the glycogen-associated protein phosphatase-1 (PPG-1) which in turn dephosphorylates and activates glycogen synthase. In this way, the MAP kinase pathway has the potential to interact with metabolic signaling pathways (see later). However, the MAP kinase pathway is not necessary for stimulation of glucose transport, and is not viewed as being critically related to the metabolic effects of insulin. For example, inhibition of the pathway in adipocytes using dominant negative forms of Ras [62] or inhibitors of MAPKK [63] will block transcriptional effects associated with the MAP kinase pathway, but will not interfere with insulin stimulation of either glucose transport or glycogen synthesis.

Figure 12.2 Metabolic and mitogenic signaling pathways in insulin action. Abbreviations: DAG, diacylglycerol; IP3, inositol-3-phosphates; $PI(3,4)P_2$, phosphatidylinositide 3,4 diphosphate; $PI(3,4,5)P_3$, phosphatidylinositide 3,4,5 triphosphate; PI-3 kinase, phosphatidylinositidide-3 kinase; PDK1, phosphoinositide-dependent kinase 1; GSK3, glycogen synthase kinase 3; GS, glycogen synthase; GLUT-4, glucose transport protein 4; IRS, family of insulin receptor substrate proteins; SHIP2, SH2-containing inositol phosphatase 2; Grb2, growth factor receptor bound 2; SOS, mammalian homologue of Drosophila son-of-sevenless protein; Akt/PKB, protein kinase B; Shc, adapter protein with homology with Src and collagen; Ras, rat sarcoma protein; Gap, GTPase activating protein; MAP kinase kinase, mitogen activated protein kinase kinase; MAP kinase, mitogen activating protein kinase; PP1G, glycogen-associated protein phosphatase 1. PI-3 kinase pathways: regulation of metabolism and gene expression

Phosphatidylinositide-3 kinase

Signal transduction for insulin's metabolic effects also diverges from insulin receptor substrate proteins and proceeds via the PI-3 kinase pathway (Figure 12.2). The first committed step involves type 1A PI-3 kinase, a heterodimer consisting of a p85 regulatory subunit and a p110 catalytic subunit [64]. In quiescent cells, the regulatory subunit maintains a state of low activity for the catalytic subunit. Upon insulin-mediated tyrosine phosphorylation, IRS-1 and IRS-2 (and other docking proteins) bind PI-3 kinase via interaction with the SH-2 domain on the p85 regulatory subunit [65]. Insulin stimulation increases the amount of PI-3 kinase associated with IRS, and the binding process increases the specific activity of the p110 catalytic subunit. Activation of PI-3 kinase is critical for transducing the metabolic actions of insulin, including stimulation of GLUT4 translocation to the plasma membrane with subsequent

stimulation of glucose transport activity. This has been demonstrated in several lines of investigation. Treatment of adipocytes with (i) inhibitors of PI-3 kinase including wortmannin or LY-294002, (ii) hyperexpression of dominant negative mutants of PI-3 kinase that interfere with endogenous wild-type enzyme function, and (iii) microinjection of neutralizing antibodies to the p110 catalytic subunits all result in abrogation of insulin's biologic effect [9]. Conversely, hyperexpression of wild-type PI-3 kinase or a constitutively active mutant leads to stimulation of both glucose transport activity and GLUT4 translocation from 50–100% of insulin's maximal effect depending on the study [66].

Several proteins can serve as the regulatory subunit of PI-3 kinase [28]. Multiple isoforms arise through alternative splicing of the p85α gene (p85α, p55α/AS53, and p50α each occurring with and without a spliced insert), and two other isoforms represent products of different genes (p85β, p55^{PIK}). All regulatory subunit isoforms associate with IRS phosphotyrosines and mediate activation of the associated p110

catalytic subunit. While p85α is ubiquitously expressed and is the dominant form in many tissues, the other isoforms exhibit differential tissue-specific expression. The various isoforms of the regulatory subunit could serve to modulate or direct signal transduction via different affinities for IRS proteins or differences in subcellular compartmentalization. In fact, studies have further illuminated novel mechanisms of regulation that involve different regulatory subunits of PI 3-kinase, and it has also become clear that the relative abundance of catalytic and regulatory subunits can influence insulin action [67–73]. For example, investigators have explored the roles of p85α (Pik3r1) and p85β (Pik3r2) regulatory subunits by using brown adipose cell lines with disruption of these genes [72]. These studies revealed key differences in the way the p85 regulatory subunit isoforms influence downstream signaling effects. Other studies have demonstrated that the balance between p85α regulatory and p110 catalytic subunit abundance regulates both insulin and IGF-1 signaling [71]. These data suggest that lowering the abundance of the p85α regulatory subunit can enhance insulin sensitivity and could present a new therapeutic target for insulin resistance.

The function of the activated PI-3 kinase is to phosphorylate the inositol ring in plasma membrane glycolipids at the D-3 position, thereby converting phosphatidylinositol 4,5 bisphosphate to phosphatidylinositol 3,4,5 trisphosphate (PI(3,4,5)P$_3$),

and to a lesser extent phosphatidylinositol 4-phosphate to phosphatidylinositol 3,4 bisphosphate (PI(3,4)P$_2$) [74,75]. In skeletal muscle, the PI-3 kinase inhibitor, wortmannin, has been shown to prevent both the formation of 3′ phospholipids and block stimulation of glucose uptake in response to insulin. While the proximal physiologic targets for the D-3 phosphoinositides have not been fully elucidated, phosphorylation of the inositol ring at the 3′ position in membrane glycolipids recruits certain signaling proteins with pleckstrin homology domains to the plasma membrane. Binding to membrane-associated phosphoinositides both activates these proteins and positions them for downstream signal transduction. In addition, phospholipase C may participate in the release of the 3′ inositol phosphate moieties and may be activated by insulin through an IRS-independent mechanism [76,50], although siRNA-based protein knockdown of phospholipase Cγ did not affect insulin signaling to the glucose transport system in 3T3-L1 adipocytes [77].

While the role of PI-3 kinase in stimulation of glucose transport has been widely recognized, it has also become clear that PI-3 kinase activation is necessary for mediating multiple other metabolic effects of insulin including regulation of gene transcription. Thus, PI-3 kinase is the second major step, downstream of insulin receptor substrates, providing for broad divergence of insulin signal transduction, as illustrated in Figure 12.3. This is well demonstrated by experiments wherein suppression

Figure 12.3 Three major steps providing for functional divergence of insulin signal transduction. The insulin receptor substrate docking proteins, PI-3 kinase, and Akt/PKB are sequentially activated by insulin, but then each factor engages multiple downstream signal molecules and pathways resulting in divergence, capacity for interaction, and complementarity of insulin signaling pathways. Abbreviations: APS, adaptor protein containing PH and SH2 domains; IRS, insulin receptor substrate protein; Gab-1, GRB-2-associated binding protein 1; Shc, adapter protein with homology with Src and collagen; PI(3,4,5)P$_3$, phosphatidylinositide 3,4,5 triphosphate; mTOR, mammalian target of rapamycin; p70^{S6K}, p70 S6 kinase; Akt/PKB, protein kinase B; aPKC, atypical protein kinase C isoforms; GSK3, glycogen synthase kinase-3; BAD, Bcl2 antagonist of cell death; NO, nitric oxide. (For a color version of this figure, please see color plate section.)

of PI-3 kinase has been shown to impact a host of insulin bioeffects including stimulation of glucose transport, glycogen synthesis, and glycolysis; promotion of lipogenesis via effects on fatty acid synthase and acetyl CoA carboxylase; suppression of gluconeogenesis; stimulation of protein synthesis; stimulation of DNA synthesis; attenuation (e.g. phosphoenolpyruvate carboxykinase (PEPCK) and glucose-6-phosphatase) and induction (e.g. glucose-6-phosphate dehydrogenase and hexokinase II) of gene transcription; cell survival; and cell cycle progression. In order to propagate many of these effects, PI-3 kinase activates three serine-threonine kinases and their downstream pathways, namely, Akt or protein kinase B (Akt/PKB), atypical PKC isoforms (ζ,λ), and phosphoinositide-dependent kinases (PDK1 and PDK2).

3-Phosphoinositide-dependent protein kinase-1 (PDK1)

Insulin-mediated activation of PI-3 kinase and generation of $PI(3,4,5)P_3$ in membrane glycolipids results in the recruitment of AGC superfamily members (protein kinase A/protein kinase G/protein kinase C family) which contain pleckstrin homology domains. This activates these serine/threonine protein kinases and positions them for downstream signal transduction. With regard to insulin signaling, the most critical of the AGC kinases activated by interaction with $PI(3,4,5)P_3$ is the PDK1, which participates in the downstream activation of Akt/PKB and aPKCs.

The AGC superfamily includes Akt/PKB and atypical PKCs.

Akt/protein kinase B

There are three isoforms of Akt/PKB; Akt1 is expressed in a variety of tissues, while Akt2 is most highly expressed in adipocytes and Akt3 in certain cultured cell models [78–81]. Phosphorylation and activation of Akt/PKB isoforms involve both 3′ phosphoinositides and the action of PDK. 3′ Phosphoinositides in membrane glycolipids bind directly to the PH domain of Akt/PKB, and this process results in the uncovering of phosphorylation sites. At the same time, 3′ phosphoinositides activate PDK1, which in turn phosphorylates the activation loops of Akt/PKB on Thr^{308}, enhancing the activity of the kinase [82]. However, Akt/PKB requires a second phosphorylation on Ser^{473} for full activation, and this could be accomplished in either of three ways. This could arise through the action of another putative phosphoinositide-dependent protein kinase, PDK2, or could be accomplished by PDK1 following a change in substrate recognition that results from threonine 308 phosphorylation, or may be the consequence of autophosphorylation. Recently, it has been suggested that rapamycin insensitive companion of mTOR (rictor) is necessary for the Ser^{473} phosphorylation step [83].

Regardless of the mechanism of phosphorylation, there are several lines of evidence that implicate a role for Akt/PKB activation in the stimulation of glucose transport. Expression of constitutively active membrane-bound forms of Akt results in persistent translocation of GLUT4 to the plasma membrane in muscle, fat, and cultured cell systems [84]. Interestingly, insulin stimulation is accompanied by association of Akt2 with GLUT4-containing vesicles in rat adipocytes resulting in phosphorylation of constituent proteins [85]. Conversely, cellular introduction of neutralizing antibodies, substrate peptides, and dominant negative mutant blocked insulin-stimulated GLUT4 translocation in adipocytes, albeit by only ∼50%. These experiments constitute strong evidence for a role of Akt/PKB in insulin stimulation of glucose transport. However, these results are somewhat controversial because other investigators demonstrated that a dominant-interfering mutant, while blocking insulin-stimulated protein synthesis, did not inhibit GLUT4 translocation [86]. Furthermore, in muscle from insulin-resistant diabetic humans, insulin-stimulated Akt phosphorylation was intact despite gross impairment in glucose uptake [87]. These discrepant results regarding a role for Akt/PKB do not exclude a role in the stimulation of glucose transport, perhaps working in concert with parallel activating pathways (e.g. PKC λ/ζ, CAP/Cbl/TC10). Mice deficient in Akt2 exhibit mild insulin resistance in muscle, glucose intolerance, and an inability to suppress hepatic glucose production, whereas Akt1 gene disruption produces growth reduction but has little effect on glucose tolerance [88,89]. These results are indicative of an important role for Akt/PKB in insulin regulation of glucose homeostasis and also suggest that Akt1 and Akt2 may compensate for each other's absence to varying degrees. Nevertheless, the downstream targets of Akt/PKB connecting this signaling pathway to stimulation of the glucose transport effector system have not been identified with certainty.

Akt/PKB activation is involved in multiple other insulin responses [89]. One of the first substrates identified for Akt/PKB was a serine 9 residue in glycogen synthase kinase 3β (GSK3β) [90,91]. Thus, one pathway that could contribute to insulin-stimulated glycogen synthesis involves Akt/PKB-mediated phosphorylation and inactivation of glycogen synthase kinase 3β resulted in activation of glycogen synthase activity (see Chapters 13 and 14 concerning regulation of carbohydrate metabolism). Akt/PKB is also capable of phosphorylating and activating mammalian target of rapamycin (mTOR), which in turn phosphorylates 4E-BP1/PHAS-1, leading to release of translation initiation factor eIF-4E, and recruitment of mRNA to the 40S ribosomal subunit [92]. The ribosomal S6 protein ($p70^{S6K}$) is phosphorylated and activated either through PDK1, Akt/PKB, or mTOR, and similarly enhances translation of select populations of mRNA by increasing their interaction with the 40S ribosome [93]. In this way, Akt/PKB helps mediate insulin's effect to stimulate protein synthesis (see Chapter 16: Insulin regulation of protein metabolism). Another apparent action is the phosphorylation and activation of endothelial NO synthase leading to increased NO generation and vasodilatation [94]. Additional substrates for Akt/PKB include BAD and caspase-9, which are involved in anti-apoptotic effects and alteration of cell survival pathways [95]. Finally, Akt/PKB phosphorylates forkhead transcription

factors [96,97] altering expression patterns of genes involved in carbohydrate and lipid metabolism. In fact, the gene regulatory effects of MAP kinase and Akt/PKB-activated forkhead transcription factors generally oppose each other. In this way, Akt/PKB represents an important mechanism for "cross-talk" between the PI-3 kinase pathway, and other pathways regulating gene transcription and mitogenic effects, in the web of insulin signal transduction (Figure 12.3).

Protein kinase C

The IRS/PI-3 kinase pathway also activates PKCζ and PKCλ, two serine-threonine protein kinase C isoforms in the "atypical" class that is not activated by calcium binding, diacylglycerol, or, phorbol esters [98,99]. PI-3 kinase-dependent activation of PKC ζ/λ has been observed in multiple target tissues and cultured cell models in response to insulin [100]. The activation of PKC ζ/λ occurs proximal to Akt/PKB as a result of direct interaction with 3′ phosphoinositides and/or through phosphorylation and activation by PDK1, which phosphorylates PKCζ on Thr[410] enhancing the activity of the kinase [82]. This is relevant to the stimulation of glucose transport since overexpression of constitutively active forms of PKCζ or PKCλ increase glucose transport activity and GLUT4 translocation by 50–100% of the extent observed in response to maximal insulin [100]. Also, expression of dominant-interfering PKC mutants, lacking a critical lysine in the kinase domain or at the site phosphorylated by PDK1, inhibits insulin's ability to promote glucose transport and GLUT4 translocation by ~50%. As is common in the insulin action field, discrepant results have also been reported where overexpression of wild-type or dominant negative mutant forms in adipocytes did not affect basal or insulin-stimulated glucose transport [101]. This type of recurring controversy indicates that hyperexpression and gene knockout experiments should be interpreted cautiously especially when expression levels are altered well above or below the physiologic range, and also reflects overlapping and complementary pathways that comprise the web of insulin signal transduction. Nevertheless, on balance, available data indicate that PKC ζ/λ does participate in insulin's metabolic signaling pathways [100]. As is the case for Akt/PKB, the downstream targets of PKC ζ/λ have not been fully identified, and this will be necessary for understanding of the relative participation of these two signaling proteins in the stimulation of glucose transport and other metabolic effects. Atypical PKCs can also mediate insulin simulation of general protein synthesis in a rapamycin-insensitive manner [102].

Degradation of the PI-3 kinase signal

At least two different types of phosphatases can degrade phosphoinositides leading to deactivation of the PI-3 kinase signal [75]. Overactivity of these enzymes has the potential for inhibiting insulin signal transduction distal to the generation of 3′ phosphoinositides and causing insulin resistance. Src-homology 2-containing inositol phosphatases (SHIP1

and SHIP2) dephosphorylate the 5′ position of PI(3,4,5)P$_3$ to form PI(3,4)P$_2$. Genetic disruption and loss of SHIP2 results in a marked increase in insulin sensitivity, implying that PI-3 kinase-mediated formation of PI(3,4,5)P$_3$, rather than PI(3,4)P$_2$, is the critical 3′ phosphoinositide in insulin signaling. Another phosphatase, phosphatase and tensin homologue (PTEN), dephosphorylates the 3′ position converting PI(3,4,5)P$_3$ to PI(4,5)P$_2$. Some human cancers are associated with loss of PTEN expression suggesting that unrestrained production of 3′ phosphoinositides could result in oncogenesis.

PI-3 kinase-independent pathways for stimulation of glucose transport

The CAP/Cbl/TC10 pathway

Substantial evidence confirms the presence of PI-3 kinase independent pathways for stimulation of glucose transport. It had long been clear that other growth factor receptors (i.e., the platelet-derived growth factor (PDGF) receptor, cytokine receptors such as IL-4, and certain integrins) activate PI-3 kinase to the same extent as the insulin receptor with generation of PI(3,4,5)P$_3$, yet still do not stimulate glucose transport [103,104]. Since stimulation of transport was blocked by PI-3 kinase inhibitors (e.g. wortmannin), investigators concluded that PI-3 kinase is necessary but not sufficient for this key metabolic effect of insulin [105]. The additional factor that endows the insulin receptor with the specific capacity to stimulate glucose transport could include another parallel signaling pathway, compartmentalization of the PI-3 kinase response, or the utilization of specific signal protein isoforms in insulin target cells.

Multiple observations support a second parallel complementary pathway for insulin-stimulated glucose transport [105,106]. For example, adenovirus-mediated hyperexpression of dominantly interfering PH and PTB domains blocks insulin receptor/IRS interaction and inhibits some responses involving PI-3 kinase, such as membrane ruffling and DNA synthesis, without any effect on GLUT4 translocation. Similarly, blockade of PI-3 kinase activation, via prolonged pretreatment with PDGF or overexpression of GSK3β, inhibits association of PI-3 kinase with IRS proteins without affecting stimulation of glucose transport or GLUT4 translocation. In addition, specific mutations in the insulin receptor have been identified that exhibit a near normal ability to activate PI-3 kinase but completely fail to induce GLUT4 translocation [107]. Finally, introduction of a cell permeable analogue of PI(3,4,5)P$_3$ does not have any effect to stimulate basal glucose transport, but in the presence of wortmannin plus insulin does elicit a maximal glucose transport response [108]. These data indicate that insulin signaling requires a separate wortmannin-insensitive pathway, which must operate in parallel with the PI-3 kinase pathway, for stimulation of glucose transport.
Figure 12.4 Two complementary pathways for stimulation of GLUT4 translocation. IRS-1, insulin receptor substrate-1; SHIP2, SH2-containing inositol phosphatase 2; PI-3 kinase, phosphatidylinositide-3 kinase; PKC, protein kinase C; Akt/PKB, protein kinase B; PDK1, phosphoinositide-dependent kinase 1; APS, adaptor protein containing PH and SH2 domains; CAP, c-Cbl associating protein; Cbl, Cbl proto-oncogene; CrkII, Crk oncogene; C3G, guanine nucleotide-releasing protein C3G; TC10, ras-like protein TC10; CIP4/2, Cdc42-interacting protein; GTP, guanosine triphosphate; GDP, guanosine diphosphate. (For a color version of this figure, please see color plate section.)

Evidence has accumulated strongly supporting the CAP/Cbl/TC10 pathway as the complementary pathway for insulin-stimulated glucose transport [105,106], as illustrated in Figure 12.4. This pathway was elucidated as a linear sequence of interacting factors using technologies such as the yeast two-hybrid system and co-immunoprecipitation of interacting factors. The pathway diverges from the PI3-kinase pathway at the level of the insulin receptor kinase, which mediates tyrosine phosphorylation of Cbl proto-oncogene through a process that does not involve IRSs. c-Cbl phosphorylation does require another adapter protein, APS, which binds the insulin receptor via SH2 domain-phosphotyrosine interaction and couples the receptor to Cbl [109]. c-Cbl is also complexed with another adapter protein, the c-Cbl associating protein (CAP), which helps facilitate recruitment of CAP/Cbl to the microdomain of the insulin receptor [110]. Tyrosine phosphorylation of Cbl results in disengagement of the CAP/Cbl complex from the insulin receptor.

CAP contains three tandem SH3 domains in the COOH-terminus that binds to a proline-rich domain of Cbl, and, in the NH2-terminal region, also contains a sorbin homology (SoHo) domain. After disengagement of CAP/Cbl from the insulin receptor, the CAP SoHo domain binds to flotillin in caveolin-containing lipid raft domains of the plasma membrane [111]. Lipid rafts are plasma membrane domains, enriched in

cholesterol, glycolipids, and sphingolipids, which coordinate signaling events by accumulating specific protein constituents. One class of lipid rafts contains caveolin proteins in invaginated structures referred to as caveolae ("little caves"). Flotillin is anchored in lipid raft domains via its interaction with caveolin proteins. Thus, CAP is responsible for relocation of the CAP/Cbl complex to lipid raft domains. Once bound to flotillin, tyrosine phosphorylated Cbl presents a recognition site for recruitment of the CrkII-C3G complex to the lipid raft. CrkII is a small adapter protein that contains an SH2 domain that binds phosphorylated Cbl, and SH3 domains that interact with a proline-rich region of C3G. C3G is a guanyl-nucleotide exchange factor for TC10 and other small molecular weight GTP binding proteins [112]. TC10 is a member of the Rho family of GTPases, and is also targeted to lipid raft domains as a result of its capacity to undergo posttranslational modification by farnesylation and palmitoylation [113]. Insulin-mediated recruitment of C3G to the lipid raft results in the activation of TC10 via GTP exchange for GDCIP4/2P. TC10 in turn interacts with and recruits Cdc42-interacting protein4/2 (CIP4/2) to the lipid raft [114]. The signaling events between TC10-CIP4/2 and translocation of GLUT4-containing vesicles have not yet been elucidated. It is tempting to hypothesize that TC10, as a Rho family member, participates in the regulation of the actin cytoskeleton, given that investigators have demonstrated

a functional requirement for filamentous actin in GLUT4 translocation [115].

Experiments involving transgene expression in adipocytes have provided strong support for the contribution of the CAP/Cbl/TC10 pathway. Deletion of CAP SH3 domains creates a dominant-interfering mutant that blocks binding to Cbl and recruitment of Cbl to lipid rafts, and prevents GLUT4 translocation and stimulation of glucose transport without loss of PI-3 kinase or MAP kinase activation [39]. SoHo deletion mutations in CAP, which prevent binding of the CAP/Cbl complex to flotillin in lipid rafts, also block GLUT4 translocation and glucose transport stimulation [116]. Hyperexpression of C3G potentiates insulin action and shifts the insulin dose–response curve to the left [112]. Overexpression of TC10 (but not other Rho family members) results in miss-targeting to nonlipid raft regions of the plasma membrane, and inhibits recruitment of GLUT4 translocation associated with disruption of cortical actin in adipocytes [113]. Mutant forms of CIP4/2 also inhibit GLUT4 translocation. To illustrate the dependence on caveolin-containing lipid rafts, disruption of rafts by cholesterol-extracting drugs (β-cyclodextrin) or by expression of mutant caveolins blocks insulin stimulation of TC10 and glucose transport [117,118]. These experiments demonstrate that the CAP/Cbl/TC10 pathway is necessary for insulin stimulation of glucose transport. However, it is important to emphasize that these findings are well established in the adipocyte system, whereas, in muscle cells, a definitive role for the CAP/Cbl/TC10 pathway has yet to be firmly established.

In future research, it will be important to elucidate the mechanisms by which activation of Akt/PKB, PKC ζ/λ, and TC10 interact with insulin's metabolic effector systems and, in particular, with the trafficking and translocation of GLUT4 vesicles (see later). Detailed study of these processes will be necessary to better define defects causing insulin resistance in human disease.

Muscle contraction

Acute exercise or muscle contraction results in GLUT4 translocation and stimulates muscle glucose transport activity [119]. This effect occurs without any change in serum insulin concentrations and does not involve activation of PI-3 kinase or Akt/PKB. The mobilization of GLUT4 to the cell surface by acute exercise may involve a different intracellular pool of GLUT4 than that recruited by insulin, and the effects of acute exercise and insulin are partially additive [119]. These observations indicate that signaling systems mediating glucose transport stimulation are different in response to acute exercise versus insulin [120]. This is underscored by the finding that, in muscle from insulin resistant humans and rodents, GLUT4 translocation is impaired in response to insulin but normal in response to acute exercise.

While signal transduction mechanisms are not fully understood, this response to acute exercise appears to be at least partially dependent on increments in intracellular 5′ AMP induced by acute exercise, and subsequent activation of 5′ AMP-activated protein kinase (AMPK) [120–122]. Hypoxia and mitochondrial uncoupling agents also increase 5′ AMP levels and increase cellular glucose transport rates. Investigators in this field have made frequent use of 5-amino-imidazole-4-carboxamide-1-β-D-riboside (AICAR), which acts as a 5′AMP analog by being phosphorylated after cellular uptake and then activating AMPK. AICAR administration mimics acute exercise by stimulating both GLUT4 translocation and glucose transport in a PI-3 kinase independent manner [121,122]. AMPK is an enzyme consisting of one catalytic subunit (α) and two regulatory subunits (β and γ), and exhibits a complex mechanism of regulation that "senses" fuel status in the cell. When ATP levels are low and 5′ AMP is elevated, AMPK activates pathways for ATP regeneration and limits further ATP utilization by modifying activity of multiple metabolic enzymes, including acetyl-CoA carboxylase, hydroxymethyl glutaryl-CoA reductase, creatine kinase, and hormone-sensitive lipase [123]. Subsequent studies using AMPK-inactive mouse models confirmed the importance of this pathway *in vivo* [124].

AS160

Downstream mechanisms leading to translocation of a distinct intracellular GLUT4 pool following muscle contraction have not been fully identified. However, an Akt substrate of 160 kDa (AS160) was identified as part of the signaling network for insulin and Akt leading to GLUT4 translocation [124–126]. Insulin-stimulated phosphorylation of AS160 was demonstrated, and this was sensitive to PI-3 kinase inhibition, placing AS160 in the pathway of insulin-stimulated GLUT4 translocation [126]. In addition, AICAR-stimulated phosphorylation of AS160 was ablated in AMPK-inactive mice [127]. Together, these studies identified AS160 as a point of convergence in insulin-mediated and contraction-mediated GLUT4 translocation. Subsequent investigation revealed that AS160 has a complex pattern of serine/threonine phosphorylation that may define its specificity [128–130].

Subsequently, AS160, designated as gene TBC1D4, was identified as a Rab GTPase activating protein [131] that serves to retain GLUT4 intracellularly, and its activation by either insulin or contraction-mediated signaling releases GLUT4 and allows it to be translocated to the plasma membrane. Rabs are key elements in vesicle trafficking pathways [132–134] that toggle between active and inactive forms through GTP loading and hydrolysis, respectively. The finding that AS160 is a Rab GTPase places it squarely in the machinery of vesicle trafficking. More recently, there is evidence that AS160 plays two roles; one, in which unphosphorylated AS160 restrains GLUT4 translocation, and a second, where phosphorylation of AS160 can facilitate fusion of GLUT4 vesicles with the plasma membrane [131].

Table 12.1 The GLUT gene family

Isoform designation[*]	Class[*]	HUGO gene nomenclature	Major tissue distribution	Characteristics
GLUT1	I	SLC2A1	Brain microvessels, erythrocytes, placenta, kidney	Ubiquitous, functions as basal transporter, predominates in cultured cell systems
GLUT2	I	SLC2A2	Liver, kidney, β cell, small intestine	High K_m transporter
GLUT3	I	SLC2A3	Brain, placenta, fetal muscle	Low K_m transporter, found in tissues metabolically dependent on glucose
GLUT4	I	SLC2A4	Skeletal muscle, adipocytes, heart	Sequestered intracellularly and translocates to cell surface in response to insulin
GLUT5	II	SLC2A5	Testes, small intestine	High affinity for fructose
GLUT6	III	SLC2A6	Spleen, leukocytes, brain	Transports glucose
GLUT7	II	SLC2A7	Unknown	
GLUT8	III	SLC2A8	Testes, blastocyst, brain	Transports glucose, mediates insulin-stimulated glucose transport in blastocyst
GLUT9	II	SLC2A9	Liver, kidney	
GLUT10	III	SLC2A10	Liver, pancreas	
GLUT11	II	SLC2A11	Heart, muscle	Fructose-inhibitable glucose transport
GLUT12	III	SLC2A12	Heart, prostate	
GLUT13	III	SLC2A13	Brain	Myoinositol transporter, also referred to as HMIT
GLUT 14		SLC2A14	Testes	Alternatively spliced long form and short form which is a duplicon of GLUT3

[*]Isoform designation and class conforms to nomenclature proposed by Joost HG et al.: *American Journal of Physiology* 2002;**282**:E974–E976.
Note: Four untranslated pseudogenes have been reported including a pseudogene previously designated as GLUT6.

The glucose transport effector system

GLUT4 vesicle translocation and trafficking

Glucose transport proteins are the key functional units of the glucose transport effector system. Multiple glucose transporter genes have been identified [66,135] that encode a family of homologous proteins exhibiting different functional properties and marked differences in tissue-specific expression. Members of the GLUT gene family are delineated in Table 12.1. On the basis of hydrophobicity plots, GLUT proteins contain 12 α-helical transmembrane-spanning domains with both the NH_2 and COOH terminals extending into the cytoplasm. This model forms six exofacial loops and five endofacial loops. Regarding GLUT1-4 isoforms (class I in Table 12.1), the five endofacial loops include a large hydrophilic central loop, while the first exofacial loop is the largest and contains an asparagine-linked glycosylation site (N57). GLUT4 glycosylation first occurs in the ER, and as GLUT4 travels on to the Golgi apparatus, additional glycan modification can occur in a multistep process, producing multiple versions of GLUT4, distinguishable from each other due to alternative side chain branching or differences in chain length. Alternatively N-glycosylated versions of GLUT4 may explain why GLUT4 differentially migrates during SDS-PAGE separation [136]. A full glycosylation profile of GLUT4 has been shown to be very important for GLUT4 protein stability [136,137] and GLUT4 localization [138]. Thus, GLUT proteins are intimately embedded in membranes, and the most highly conserved regions are the putative membrane-spanning domains that serve a common function, the creation of a pore for facilitative diffusion of monosaccharides.

The major insulin-responsive glucose transporter isoform is GLUT4, which is predominately expressed in insulin target tissues such as skeletal and cardiac muscle and adipose tissue. In the basal state, GLUT4 is predominantly localized intracellularly. The major mechanism by which insulin activates glucose transport activity is by recruiting intracellular GLUT4 to the plasma membrane, which results in facilitative diffusion of glucose into the cell where glucose is rapidly phosphorylated by hexokinase and metabolized. Importantly, the glucose transport step is rate-limiting for insulin-stimulated glucose uptake and metabolism in peripheral target tissues under physiologic conditions [135]. Upon dissipation of the insulin signal, deactivation of glucose transport activity is the result of a net reverse translocation of GLUT4 back into the cell interior.

Based on subcellular membrane fractionation experiments, insulin-mediated translocation was initially conceptualized as a two-compartment process with recruitment of GLUT4 from Golgi-enriched microsomal membranes to the plasma membrane. However, these studies consistently indicated that only ~50–60% of microsomal GLUT4 translocated to the plasma membrane fraction, suggesting that there were both insulin responsive and nonresponsive intracellular pools. It is now clear that GLUT4 trafficking involves multiple intracellular membrane compartments [66,105,139,140]. GLUT4 protein is synthesized in the endoplasmic reticulum and travels to the trans-Golgi network (TGN), where GLUT4 is then inserted into

highly specialized vesicles. In basal cells, morphologic studies employing immunohistochemistry and electron microscopy have detected GLUT4 in the perinuclear TGN, in cytosolic tubulovesicular elements, and in subplasma membrane vesicles. In one study, disruption of the TGN using the antibiotic brefeldin A did not impair insulin-stimulated glucose transport activity or surface appearance of GLUT4, ruling out TGN-based GLUT4 as being part of insulin-stimulated glucose uptake [141]. GLUT4 was shown to be largely recruited from small vesicles (GLUT4 storage vesicles, or "GSVs" [142]) located near the endofacial surface of the plasma membrane [141]. Other morphologic data have implicated tubulovesicular structures as the source of the translocating GLUT4 pool [139]. In addition to the GSV pool, GLUT4 also cycles through an early endosomal compartment in an endocytotic/exocytotic pathway (distinct from fluid-phase endocytosis) analogous to that described for other insulin-responsive proteins, such as the mannose-6-phosphate/insulin-like growth factor 2 receptor and the transferrin receptor. GLUT4 in the endosomal recycling system is clearly distinct from the intracellular, insulin-inducible GLUT4 storage compartment [143–147]. For example, ablation of the recycling compartment, accomplished via internalization of a transferrin-horseradish peroxidase conjugate, eliminates vesicles containing transferrin receptors and VAMP3/cellubrevin (endosomal markers) but leaves intact a large fraction of GLUT4-containing vesicles. There are two models for GLUT4 localization post-TGN: (1) the dynamic retention model states GSVs cycle between the specific, insulin-sensitive GSV compartment and the endosomal recycling pool, and (2) the static retention model which proposes GSVs are locked in place until insulin signals the release of the GSV for subsequent membrane translocation. Within both models, GSVs are sequestered intracellularly under basal conditions, and it is the GSV, not the endosomal GLUT4, that represents the major source for insulin-mediated exocytosis and translocation of GLUT4 to the plasma membrane. This unique GSV storage compartment can explain why insulin's effect to augment cell surface proteins is much greater for GLUT4 (10–40-fold over basal) compared with IGF-1 and transferrin receptors that traffic only in the endosomal recycling pathway.

A model for GLUT4 traffic and translocation is shown in Figure 12.5 based on a consensus of current data. Following early endocytosis, GLUT4 is sorted from other receptor and channel proteins in the recycling pathway and sequestered in a unique storage compartment comprised of GSVs and tubulovesicular elements. Insulin recruits GLUT4 primarily by stimulating exocytotic fusion of GSVs with the plasma membrane resulting in exofacial exposure of functional glucose channels. In basal cells, constitutive cycling of GLUT4 between intracellular and cell surface compartments has been demonstrated which may reflect a proportion of GLUT4 remaining in the endosomal recycling pathway. Insulin increases numbers of plasma membrane GLUT4 primarily by augmenting net exocytosis and also exerts a smaller effect to retard endocytosis. Stimulation of exocytosis proceeds primarily from the GSV pool with a smaller contribution from the constitutive recycling pathway.
Figure 12.5 Cellular trafficking and itinerary of GLUT4 glucose transporter proteins. The model is based on a consensus of current data, and includes an endosomal recycling pathway, a separate intracellular inducible GLUT4 storage compartment which supplies the majority of GLUT4 recruited by insulin to the cell surface, and an alternative compartment where accumulated GLUT4 does not respond to insulin in insulin-resistant states (see text). (For a color version of this figure, please see color plate section.)

GLUT4 vesicle trafficking is directed by several factors, including targeting motifs intrinsic to GLUT4, posttranslational modifications of GLUT4, and interactions with multiple proteins known to regulate the vectorial flow of cellular vesicles and their cargo proteins. In terms of intrinsic signals, a di-leucine motif at positions 489 and 490 in the cytosolic C-terminal of GLUT4, and an aromatic-based motif (FQQI) in the NH_2 terminus, function as internalization signals for endocytosis [139,148]. While these intrinsic motifs help direct internalization, the signals for intracellular retention in the inducible storage compartment have still not been identified with certainty. Interestingly, upon mutation of the core GLUT4 glycosylation site (within the first exofacial loop at the N terminus), GLUT4 has been shown to accumulate at the cell membrane [138], while at the same time insulin-mediated translocation of intracellular GLUT4 was impaired [137], suggesting GLUT4 glycosylation plays an important role in the trafficking of the GSV. Even so, others have produced contradictory evidence showing that GLUT4 glycosylation does not affect GLUT4 vesicular trafficking [136,137,149]. Some evidence has been obtained suggesting that an acidic cluster of amino acids (TELEYLGP) downstream from the di-leucine motif is important for targeting GLUT4 to the inducible storage compartment [150]. In other experiments, overproduction of the GLUT4 C-terminus resulted in partial GLUT4 translocation and activation of glucose transport, suggesting that this peptide is interacting with an intracellular retention protein [151]. The COOH-terminus di-leucine motif is adjacent to a phosphorylation site (serine at 488) which, when mutated, can impair internalization when expressed in host cells. GLUT4 phosphorylation occurs at several residues within the large cytosolic loop between helices 6 and 7 and also at several sites within the C-terminal cytoplasmic tail. There is a lack of consensus over whether phosphorylation of GLUT4 is increased, decreased, or unaffected upon stimulation with insulin, since evidence has been shown to support all three of these possibilities [152]. Thus, the role of GLUT4 phosphorylation in response to insulin is unclear.

In addition to phosphorylation and N-glycosylation, GLUT4 undergoes ubiquitination (the addition of ubiquitin, a 76-amino acid protein) at residues localized throughout the intracellular loops of the protein, and this modification is important for GLUT4 to properly localize to the GSV [153]. GLUT4 also undergoes SUMOylation, which is the addition of the 101-amino acid protein SUMO-1, although the exact location of SUMOylation on GLUT4 is unknown. SUMOylation of GLUT4 is mediated by ubiquitin conjugating enzyme 9 (Ubc9), and was shown to considerably extend the half-life of GLUT4 protein expression, suggesting that this modification is crucial for GLUT4 protein stability [154,155]. Palmitoylation, the covalent attachment of fatty acids, of GLUT4 has also been observed [156], although the role of this posttranslational modification is unclear.

GSV traffic is controlled by multiple protein subclasses, also known to be involved in the regulated endocytosis/exocytosis of synaptic and neurosecretory vesicles [135,139,140,143–148]. Multiple trafficking proteins are actual constituents of the GLUT4 vesicle; GLUT4 vesicle cargo proteins include vesicle-associated membrane protein-2 (VAMP-2) or synaptobrevin, VAMP-3/cellulobrevin, syntaxin 4, 35-39 kDa secretory carrier-associated membrane proteins (SCAMPs), cellugyrin, acyl-CoA synthetase-1, and small molecular weight GTP binding proteins in the Rab and Arf subclasses. Of these proteins, VAMP-2, VAMP-3/cellubrevin, SCAMPs, and cellugyrin are known to be constituents of GLUT4-containing vesicles in the endosomal recycling pathway where they co-localize with IGF-1 and transferrin receptors. Of these, only VAMP-2 is present together with GLUT4 in the intracellular storage compartment. Several other constituents of the GSV are an aminopeptidase, referred to as the insulin-regulated aminopeptidase (IRAP) [157], low-density lipoprotein receptor-related protein 1 (LRP1), and sortilin, all of which contribute to promoting GLUT4 localization to the GSV [158–160]. These proteins translocate with GLUT4, while IRAP in particular has commonly been used to track the cellular itinerary of GSVs which is translocated along with GLUT4 to the plasma membrane.

The v-SNARE/t-SNARE model developed by Rothman and others explains how vesicles traffic to specific membrane compartments [161]. In this model, shown in Figure 12.6, a docking and fusion reaction is initiated via the high affinity interaction between a ligand on the transport vesicle (v-SNARE) and a receptor in the target membrane (t-SNARE). In the case of GLUT4 vesicle translocation from the inducible storage compartment to the cell surface, evidence suggests that VAMP-2 functions as the v-SNARE and syntaxin 4 as the plasma membrane t-SNARE [135,139,140,143–148]. Other proteins facilitate and regulate this interaction. The N-ethylmaleimide sensitive factor (NSF) activates the v-SNARE for docking competency, and three proteins, the soluble NSF attachment 23 kDa protein (SNAP23), the mouse Unc homologue 18c (Munc-18c), and the syntaxin4-interacting protein (Synip), regulate docking efficiency at the level of the t-SNARE by facilitating or blocking access to syntaxin4 [162]. While SNAP23, Munc18c, and Synip form a complex with syntaxin4 at the endofacial plasma membrane, their precise roles in modulating interaction between VAMP-2 and syntaxin4 are not fully understood. Synip appears to block access of VAMP-2 to syntaxin4 under basal conditions, and is released from the complex following insulin stimulation allowing docking of v-SNARE (VAMP-2) to the t-SNARE (syntaxain4). The function of Munc-18c appears to be more complex with evidence that it can both inhibit (basal conditions) and facilitate (insulin-stimulated condition) VAMP-2-syntaxin4 interaction. The Rab family of monomeric GTPases also play an important role in vesicle traffic; different isoforms are targeted to specific organelle membranes and direct the vectorial flow of vesicle proteins from one compartment to another [163,164]. Rab GTPases also appear to catalyze the union of v- and t-SNARES in the docking process. Rab4 has
Figure 12.6 Proteins regulating the docking of exocytotic GLUT4 vesicles at the plasma membrane. Abbreviations: IRAP, insulin regulated aminopeptidase; ACS-1, acyl-CoA synthetase-1; VAMP-2, vesicle-associated membrane protein 2; NSF, N-ethylmaleimide sensitive factor; SNAP-23, soluble NSF attachment 23 kDa protein; Munc-18c, mouse Unc homologue 18c; Synip, syntaxin 4 interacting protein; Rab, monomeric GTPase in the Rab subclass; t-SNARE and v-SNARE refer to target membrane and vesicle-associated soluble N-ethylmaleimide-sensitive attachment protein receptors, respectively. (For a color version of this figure, please see color plate section.)

been demonstrated to be associated with GLUT4 vesicles in basal cells, but is redistributed to cytosol in response to insulin where it associates with its GDP-association inhibitor [165]. Furthermore, Rab4 has been shown to interact with syntaxin4 *in vitro*, and overexpression of Rab4 or a COOH-terminal domain peptide, prevented insulin-stimulated GLUT4 translocation in adipocytes [166]. Undoubtedly, there are additional factors participating in GLUT4 vesicle targeting, docking, and fusion in insulin target tissues that remain undiscovered.

The cellular cytoskeleton

There is increasing recognition that GLUT4 translocation involves the actin cytoskeleton [66,167–169]. One line of evidence supporting this hypothesis is that disruption of the actin cytoskeleton by cytochalasin D or latrunculin also inhibits insulin-mediated GLUT4 translocation [167,168]. In addition, insulin stimulates cytoskeletal rearrangement, in particular the cortical actin fibers subtending the plasma membrane, and regulates molecules that control actin polymerization. Insulin-stimulated actin reorganization is dependent upon members of the small G-proteins of the Rho family [66,115], with the protein Rac1 active in muscle and both TC10 and Cdc42 in adipose tissue. Insulin stimulates GTP loading of Rac1, TC10, and Cdc42 followed by activation of the nucleation-promoting

factor (NPF) of the Wiskott–Aldrich syndrome protein (WASP) family member, N-WASP [169,170]. The WASP proteins are responsible for the binding and activation of the Arp2/3 complex. Arp2/3 then acts as the true actin nucleator by binding to an existing actin filament to create new actin branched networks. It is attractive to hypothesize that activation of TC10 via the CAP/Cbl/TC10 pathway could mediate regulation of the actin cytoskeleton in response to insulin, since TC10 and other Rho GTPases are generally known to affect biochemical modulators of cytoskeletal function [171]. However, PI-3 kinase can also affect cortical actin polymerization and events such as membrane ruffling and filopodia formation; therefore, other insulin signaling pathways, like Rac1, could also contribute to this biologic effect. The exact role of the actin cytoskeleton has not yet been delineated; however, one proposal is that actin filaments serve as a scaffold to direct GLUT4 vesicle trafficking using actin-based motility as a motor for vesicle movement.

The microtubule cytoskeleton is also involved in GLUT4 vesicle trafficking [140,172,173]. The GSV translocate along microtubule tracks to arrive at the inducible storage compartment proximal to the plasma membrane [174,175], and it is not surprising that microtubule proteins such as dynein and kinesin have been co-purified with GLUT4. Disruption of microtubules using depolymerizing agents inhibits GLUT4

translocation and glucose transport stimulation, and expression of a dominant-interfering dynein mutant was shown to inhibit GLUT4 endocytosis in a process that may require Rab5 [176]. This transport has been shown to be mediated by the cargo transport motor proteins of the kinesin family [177] including KIF5B [172] and KIF3 [178]. Upon receiving the insulin signal, tether containing UBX domain for GLUT4 (TUG) was found to disassociate from GLUT4, which has been postulated to act as the release of a "handbrake mechanism," allowing for GLUT4 to travel to the plasma membrane [179]. Upon arrival at the interior surface of the cell, the GSV undergoes the "docking" phase of translocation, through association with the exocyst complex, which has been proposed to function in the targeting of the GSV to areas on the plasma membrane rich in the proteins involved in fusion of the GSV with the membrane [180,181]. The GSV then undergoes the transition to the docking/fusion phase, which is mediated by the SNARE complex.

With the advent of real-time total internal reflection fluorescence microscopy (TIRFM), which visualizes just the first 200 nm of the intracellular surface of the cell membrane, it was confirmed that microtubules form a network directly underneath the entire plasma membrane, which was proposed to allow GSVs to scan the cytoplasmic surface of the cell membrane during the highly mobile basal state [182]. TIRFM has also shown that defective actin remodeling disrupted the exocytotic fusion step of the GSV, whereas the insulin-stimulated increase of GLUT4 vesicles proximal to the plasma membrane was not affected [183]. TIRFM performed in living 3T3-L1 adipocytes proved that insulin-stimulated fusion of GSVs occurs proximal to microtubules at the plasma membrane. This study also captured, for the first time, video evidence in living adipocytes of the substantial increase of microtubule density and curvature that occurs at the plasma membrane during insulin stimulation. The authors did find long-range movements of GSVs along microtubules, although the GSVs rarely moved long distances before fusion, suggesting that long-range GSV trafficking is not involved in insulin-stimulated GLUT4 insertion into the membrane. Nocodazole treatment, for example, did not significantly decrease the number of GSV fusion events stimulated by insulin, leading the authors to conclude that microtubules are not vital for the insertion of GSVs into the plasma membrane, but rather play a more important role in site selection for delivery of GLUT4 prior to fusion [184]. In line with this hypothesis, CLASP2, a microtubule associated protein that targets microtubules to the interior surface of the cell cortex, was found to undergo insulin stimulated co-localization with GLUT4 at the plasma membrane. This led the authors to propose that the distal end of microtubules undergo CLASP2 targeting to landing zones on the cell cortex, thereby situating microtubule-bound GSVs proximal to the plasma membrane [185]. An attractive hypothesis is that GLUT4 begins exocytosis in a microtubular compartment, and then transfers to actin scaffolds that connect the microtubule cytoskeleton with the plasma membrane, possibly through the protein actinin-4 [186], which then positions GLUT4 vesicles for docking and membrane fusion. Upon endocytosis, GLUT4 traffics in an endosomal compartment regulated by actin filaments and eventually is sorted back to the microtubular inducible storage compartment. While this model is compelling, additional research is necessary to define the role of cytoskeletal elements in GLUT4 translocation. In any case, these considerations emphasize the complex nature of the glucose transport effector system, which functionally incorporates both vesicle traffic and cytoskeletal systems.

Insulin resistance in humans: abnormalities in insulin signaling and in the glucose transport effector system

Abnormalities in insulin signaling

Although the key elements of the insulin signaling network have been defined by studies employing molecular and cell biology techniques, a number of studies have focused on translating this knowledge to human studies in a clinical research setting. Insulin resistance in peripheral tissues characterizes obesity and T2DM, and is involved in the pathogenesis of diabetes [187]. Studies using hyperinsulinemic, euglycemic clamps have demonstrated that systemic insulin resistance is associated with reduced stimulation of glucose transport in muscle and adipose tissues biopsied from these same subjects [188]. Further studies in these insulin target tissues have elucidated defects in insulin signaling as well as defects intrinsic to the glucose transport system in insulin-resistant humans.

Regarding insulin signal transduction, investigators have demonstrated reductions in insulin-stimulated tyrosine phosphorylation of both insulin receptor and IRS-1, decreased association of PI-3 kinase with IRS-1, and more modest decrements in insulin-stimulated Akt phosphorylation [189,190]. Despite these defects, insulin stimulation of ERK2 phosphorylation was normal or even elevated in muscle from patients with T2DM [189,190]. This dichotomy between insulin-stimulated PI-3 kinase and MAP kinase signaling later was extended to insulin signaling in vascular cells under conditions that produce insulin resistance [191]. The implications of this dichotomy remain unclear, but it is conceivable that maintenance of this imbalance could lead to worsening of insulin resistance through serine phosphorylation of IRS-1 by ERK [192]. To probe causal relationships, other studies employed perturbations to either enhance or diminish *in vivo* insulin sensitivity to determine if there were commensurate changes in phosphorylation/dephosphorylation of the insulin receptor, IRS-1, and PI-3 kinase. Using muscle biopsies and euglycemic clamps, investigators have shown beneficial effects of treatment with thiazolidinediones [193], exercise [194], caloric restriction [195], and tight glucose control [196]. In contrast, insulin resistance provoking treatments like infusion of a triglyceride emulsion worsened insulin signaling defects [197].

One of the methodological breakthroughs that enabled investigators to define mechanisms of phosphorylation-induced activation or inactivation of insulin signaling proteins was the use of motif-specific antibodies directed against phosphopeptide motifs present in these proteins. Although this provided a powerful and facile method approach in *in vivo* studies, there always remain questions of specificity and quantification. Furthermore, with these techniques, only changes in known phosphorylation events can be assessed. A relatively new addition to the tool kit used to analyze insulin signaling is mass spectrometry based proteomics techniques, especially applied to posttranslational modifications, and in particular, phosphorylation, due to its importance in regulating activity of signaling proteins. Mass spectrometry allows for identification of novel phosphorylation sites in known insulin signaling proteins and the discovery of new insulin signaling proteins that exhibit insulin-induced changes in phosphorylation. These techniques have proven to be invaluable for deciphering the complexity of serine and threonine phosphorylation sites in IRS proteins [198,199] and AS160 [130]. These methods allow for simultaneous quantification of many phosphorylation sites at the same time, unlike immunoblot analysis. For example, Humphries et al. were able to identify 37,248 phosphorylation sites on 5705 proteins in 3T3-L1 adipocytes, with approximately 15% responding to insulin. This led to the discovery that SIN1, a core component of the mTORC2 complex, is an Akt substrate, and the phosphorylation of SIN1 by Akt regulates mTORC2 activity in response to growth factors [200].

The glucose transport system

Given that plasma membrane glucose transport is rate-limiting for insulin-stimulated glucose metabolism in insulin target cells, defects in GLUT4 expression, diminished functional activity, or impaired translocation could readily explain insulin resistance [201]. The multicompartmental nature of GLUT4 cellular trafficking, requiring a multiplicity of regulatory proteins, indicates that there are many potential sites for defects that could impair GLUT4 translocation. Indeed, defects intrinsic to the glucose transport system have been shown to be an important cause of insulin resistance in muscle and fat tissues from insulin-resistant and diabetic patients. In adipocytes, cellular depletion of GLUT4 transporters is a major mechanism of insulin resistance in obesity and T2DM [202], while GLUT4 expression is relatively normal in skeletal muscle [203]. However, in both muscle and fat, GLUT4 accumulates or is redistributed to a dense membrane compartment under basal conditions, and this abnormality is linked to impaired GLUT4 translocation to the plasma membrane in response to insulin [204–206] (see Figure 12.6). These data are indicative of a trafficking or targeting abnormality impairing GLUT4 translocation in tissues derived from insulin-resistant subjects. Additional study of pathways and factors involved in abnormal GLUT4 traffic may elucidate mechanisms causing human insulin resistance and establish targets for drug development.

Modulation of insulin action

Important recent advances in the study of insulin signaling include the elucidation of multiple mechanisms for dampening or inhibiting insulin signal transduction. The studies have provided insight into the extensive regulation of insulin action, and have also identified potential therapeutic targets, since blocking these inhibitory mechanisms could enhance insulin sensitivity. These mechanisms are summarized in Figure 12.7.

Serine-threonine phosphorylation of the insulin receptor and IRS proteins

Serine-threonine phosphorylation of insulin receptors and insulin substrate docking proteins has emerged as a major mechanism for modulation of insulin signal transduction. Serine phosphorylation of the insulin receptor diminishes its tyrosine kinase activity [10]. Serine phosphorylation of IRS-1 (and other IRSs) decreases receptor-IRS coupling by inhibiting insulin-mediated receptor phosphorylation, tyrosine phosphorylation of IRS-1, binding and activation of PI-3 kinase, and stimulation of glucose transport [207–209]. There are consensus sequences in IRS-1 that make it susceptible to a wide variety of serine-threonine kinases including PKC, PKA, Akt/PKB, MAP kinase, GSK3, casein kinase II, Cdc2 kinase, and JKN. Several of these kinases have been shown to function as physiologic modulators causing desensitization of insulin signaling pathways [210].

Protein kinase C

Protein kinase C isoforms are categorized as classic (α,β,γ), novel ($\delta,\theta,\varepsilon,\eta,\mu$), and atypical ($\zeta,\lambda,\iota$) depending on their ability to be activated by calcium and diacylglycerol (DAG). These serine-threonine kinases can act on multiple substrates, including IRS docking proteins and the insulin receptor [10,207,208]. Serine-threonine phosphorylation of IRS impairs its ability to associate with the insulin receptor and with PI-3 kinase, resulting in desensitization of the PI-3 kinase pathway. Hyperinsulinemia, hyperglycemia, and elevated circulating free fatty acids increase intracellular DAG, which in turn activates conventional and novel PKC isoforms principally via recruitment to the plasma membrane. These conditions are associated with increased serine-threonine phosphorylation and diminished function of insulin receptors and IRS proteins. In addition, insulin activates atypical PKCs, such as PKCζ, via the PI-3 kinase pathway, and atypical PKCs are then also capable of phosphorylating and desensitizing IRS [211,212]. Thus, PKCζ could be involved both in direct promulgation (Figure 12.2) and in feedback inhibition (Figure 12.7) of insulin signal transduction.

Tumor necrosis-α (TNFα)

TNFα is a cytokine produced by immune cells and also by adipocytes and muscle tissue. While having little impact on systemic circulating concentrations, TNFα expression is increased

Figure 12.7 Mechanisms for modulation of insulin signal transduction. The figure illustrates pathways resulting in the desensitization of insulin signal transduction, including serine/threonine phosphorylation of the insulin receptor or IRS by PKC, IKKβ, or JNK; inhibition of the insulin receptor tyrosine kinase by PC-1; tyrosine phosphatase action of PTPase-1B and LAR; catabolism of 3′ phosphoinositide moieties by SHIP-2 or PTEN; inhibition of Akt/PKB activation by ceramide; and interference with substrate binding (STAT5B) to the insulin receptor β subunit by SOCS-3. Abbreviations: PC-1, plasma cell membrane glycoprotein PC-1; SOCS-3, suppressor of cytokine signaling 3; STAT-5B, signal transducer and activator of transcription 5B; PTPase-1B, protein tyrosine phosphatase 1B; LAR, leukocyte antigen-related tyrosine phosphatase; cPKC, classic protein kinase C isoforms; nPKC, novel protein kinase C isoforms; PKC-ζ, protein kinase Cζ; JNK, c-Jun N-terminal kinase; IKK-β, kinase of inhibitor of kappa light chain gene enhancer in B cells β; TNF-α, tumor necrosis factor α; IRS, insulin receptor substrate protein; ser/thr, a serine or threonine residue; Y, tyrosine residue; PI-3 kinase, phosphatidylinositide-3 kinase; SHIP-2, SH2-containing inositol phosphatase 2; PTEN, phosphatase and tensin homologue; Akt/PKB, protein kinase B. (For a color version of this figure, please see color plate section.)

in adipose and muscle tissues as a function of insulin resistance [213,214], raising the possibility that the cytokine could be inducing cellular insulin resistance via autocrine/paracrine effects. Consistent with this idea, TNFα has been shown to cause insulin resistance in cultured cell models. While the mechanisms underlying desensitization have not been fully elucidated, TNFα leads to an increase in serine phosphorylation of IRS-1, thereby decreasing both insulin receptor tyrosine kinase activity and downstream insulin signal transduction [215–217]. One possible branch of the TNFα signaling pathway that could mediate IRS phosphorylation results is the activation of the stress-induced kinase, c-JUN NH$_2$-terminal kinase (JNK). JNK is a serine kinase with many intracellular substrates including insulin receptor substrate docking proteins, IRS-1, IRS-2, Shc, and Gab-1. These docking molecules contain JNK binding motifs that facilitate JNK-mediated phosphorylation of serine residues. In the case of IRS-1, JNK action results in the phosphorylation of a serine residue (ser[307] in mice or ser[312] in humans) that lies within the PTB domain; phosphorylation at this site interferes with PTB function reducing interaction

between insulin receptor and IRS-1 [218]. Another potential mechanism involves insulin stimulation of sphingomyelinase activity causing release of ceramide from sphingomyelin in lipid raft domains [81,219]. Exogenous ceramide induces insulin resistance in cultured adipocytes associated with decreased Akt/PKB phosphorylation and GLUT4 translocation. Regardless of underlying mechanisms, abrogation of TNFα action by targeted disruption of TNFα receptor isoforms (p55 and p75) results in enhanced insulin sensitivity in mice [219].

IκB kinase-β (IKKβ)

Treatment with high doses of salicylates improves glucose tolerance and enhances insulin sensitivity in humans and rodents [220]. An important biologic effect of salicylates is the inhibition of the IKKβ. Because IKKβ is a serine kinase, these observations implicate this serine kinase cascade in desensitization of the insulin signal, perhaps through serine phosphorylation of IRS or the insulin receptor. Predictably, salicylates would then enhance insulin sensitivity by causing a subsequent decrease in IKKβ-mediated serine phosphorylation

of IRS. Consistent with this hypothesis, heterozygous ablation of the IKKβ gene in mice prevents insulin resistance induced by high-fat feeding or lipid-infusion, and in obese leptin-deficient *ob/ob* mice [221,222]. IKKβ can also activate nuclear transcription factor kappa-B (NF-κB) via phosphorylation of IκB, a physically bound inhibitor of NF-κB. Upon phosphorylation, IκB dissociates from NF-κB allowing NF-κB to enter the nucleus where it can activate multiple genes involved in inflammation, immunity, and the stress response, including TNFα. Thus, inhibition of IKKβ could also enhance insulin signaling by blocking activation of NF-κB.

Protein phosphotyrosine phosphatases

Endogenous phosphotyrosine phosphatases (PTPases) are able to dephosphorylate tyrosine residues on the insulin receptor β subunit and insulin receptor substrate docking molecules, resulting in a dampening of insulin signal transduction [223]. Membrane-associated PTPase activity is increased in skeletal muscle from patients with T2DM [224], principally due to increments in cytosolic PTPase-1B and membrane-associated leukocyte antigen-related phosphatase (LAR) [225,226]. The ability of PTPases to modulate insulin signaling has been demonstrated in mice with genetic ablation of PTPase-1B, which exhibit enhanced insulin sensitivity, increased insulin-mediated tyrosine phosphorylation of the receptor and IRS, and a failure to develop insulin resistance when fed a high-fat diet [227]. The data demonstrate that PTPase-1B is able to negatively modulate insulin signaling through dephosphorylation of tyrosine residues in the insulin receptor and IRSs. Inhibition of PTPase action represents a clinically attractive therapeutic target for increasing insulin sensitivity.

Other mechanisms
Suppressor of cytokine signaling-3

Observations pertaining to suppressor of cytokine signaling-3 (SOCS-3) point to a new mechanism for insulin signal modulation [41]. The SOCS family of proteins (CIS and SOCS 1–7) were originally described as a negative feedback loop for cytokine receptor signaling through Janus kinase (JaK). JaK phosphorylates and activates signal transducer and activator of transcription (STAT), which is a transcription factor that augments SOCS gene expression. SOCS proteins then feedback to inhibit tyrosine-phosphorylated cytokine receptors, via either competitive binding through their SH2 domain preventing phosphorylation of cytokine receptor substrates or by binding and inhibiting Jak tyrosine kinases. Evidence suggests that a similar mechanism may be operative for the insulin receptor [228]. Insulin stimulates STAT5B activation by direct tyrosine phosphorylation after STAT5B binds to insulin receptor phosphotyrosine 972 via its SH2 domain (i.e., this interaction does not involve a PTB as is the case with IRS). STAT5B induces expression of SOCS-3, which then competes with STAT5B binding to the insulin receptor inhibiting further STAT5B activation. Thus, SOCS-3 could function as a negative

regulator for insulin signaling, not only with respect to STAT5B activation, but also for other signaling pathways to the extent that SOCS-3 could prevent the interaction between the PTB domain of IRS and the insulin receptor. It is intriguing that several factors that induce cellular insulin resistance also induce SOCS-3 expression, including TNFα [229], growth hormone [230], and leptin [231].

Plasma differentiation factor-1 (PC-1)

PC-1 is a membrane glycoprotein with pyrophosphatase activity that appears to act as an intrinsic inhibitor of the insulin receptor tyrosine kinase through an undefined mechanism [232–234]. Muscle expression of PC-1 is elevated in diabetes and in obesity, and correlates with diminished insulin receptor tyrosine phosphorylation and muscle glucose uptake [235].

Regulation of gene transcription

Insulin response elements

Insulin regulates the expression of many individual proteins through effects on translation, mRNA stability, and gene transcription. The stimulatory effect on translation generally results from increases in the initial phase of translation of mRNA by ribosomes, and is discussed in Chapter 16: Insulin regulation of protein metabolism. Regulation of gene transcription can be due to effects on transcription factors that are directly modified via insulin signaling mechanisms, or that are indirect as the result of stimulation of glucose metabolism. For example, genes encoding pyruvate kinase, fatty acid synthase, acetyl-CoA carboxylase, and stearoyl-CoA desaturase require increases in both insulin and glucose for induction, and PEPCK expression can be suppressed independently by insulin or glucose. The promoter elements (*cis* acting sequences) that mediate changes in gene transcription are referred to as insulin response sequences (IRS) or insulin response elements (IRE). There clearly exist multiple distinct classes of IREs that participate in the regulation of different gene promoters, rather than a single consensus nucleotide sequence [236]. These IREs can mediate either positive effects (GAPDH, pyruvate kinase, fatty acid synthase, somatostatin, c-fos, glucokinase, apoA1) or negative effects (e.g. PEPCK, glucose-6 phosphatase, tyrosine aminotransferase, apoCIII, glucagon) on gene transcription. It is also important to consider the identity of the transcription factors (*trans* acting factors) activated by insulin that bind to the IREs and alter gene transcription rates. While the identification of transcription factors has progressed more slowly than with IREs, there has been progress in identifying transcription factors and signaling mechanisms involved in insulin regulation of specific genes.

Insulin regulation of gene expression has been most readily attributed to the mitogenic MAP kinase pathway. However, insulin inhibition of PEPCK, IGFBP-1, and glucose-6 phosphatase genes employs the PEPCK-like IRE with consensus

sequence T(G/A)TTT(T/G)(G/T) in the core motif, and this occurs through a PI-3 kinase-dependent pathway [236]. The downstream targets of PI-3 kinase are somewhat controversial with studies arguing for and against the involvement of Akt/PKB and a recent study supporting a role for GSK-3 in the inhibition of PEPCK and glucose-6-phosphatase genes [237]. Nevertheless, PI-3 kinase pathways can also regulate gene transcription, and this calls into question notions of distinct and separate metabolic and mitogenic insulin action pathways in the web of insulin signal transduction.

TPA and serum response elements

The ability of insulin to alter gene expression via the mitogenic MAP kinase pathway has long been recognized [238]. This classic mechanism involves phosphorylation of transcription factors in the activating protein-1 (AP-1) family such as c-Jun and c-fos which interact with the TPA response element (TRE), and ternary complex factors such as Elk-1, SAP-1, and SAP-2 which interact with the serum response element (SRE). Both elements can be found in single gene promoters, for example, in the c-fos gene which is induced by insulin through activation of both c-Jun and Elk-1.

Forkhead transcription factors

Genetic studies in the nematode, *Caenorhababtidis elegans*, have led to the discovery of an additional pathway for insulin-regulated gene expression [239]. One of the developmental stages in *C. elegans* is the *dauer* stage characterized by increased longevity, reduced metabolic activity, and increased body fat. A series of specific gene mutations, termed Daf alleles, has defined a signal transduction pathway leading to a constitutive *dauer* phenoptype. Daf genes include the homologues of the insulin/IGF-1 receptor, PI-3 kinase, PDK-1, and Akt/PKB isoform genes in mammals, as well as Daf-16 which encodes a transcription factor with homology to the mammalian forkhead family of transcription factors. Forkhead transcription factors were first identified as being involved in the forkhead mutation in *Drosophila*, and the subclass of mammalian forkhead proteins with greatest homology to Daf-16 was first identified in alveolar rhabdomyosarcoma; this latter subclass is referred to as forkhead in human rhabdomyosarcoma (FKHR). The FKHR family is comprised of three expressed genes, FKHR or FOXO1, FKHRL1 or FOXO3, and AFX or FOXO4 [240]. FOXO1 is the most highly expressed FKHR isoform in insulin-responsive tissues such as liver, adipose tissue, and pancreatic β cells.

In nematodes and in mammals, the FKHR proteins represent an important signal transduction pathway by which insulin receptors modulate gene expression. Insulin stimulation results in PI-3 kinase-dependent phosphorylation of FKHR transcription factors by Akt/PKB at three different phosphorylation sites (Thr-24, Ser-256, and Ser-319 in FOXO1) [240]. Under basal conditions, FKHR proteins reside within the nucleus, but, upon phosphorylation, dissociate from their DNA binding site, and are then excluded from the nucleus and retained in the cytosol.

Replacement of Thr-24 or Ser-256 by alanine results in loss of phosphorylation by Akt/PKB, lack of FOXO1 nuclear export, and failure of insulin-mediated promoter suppression [241]. The relocation of FKHR out of the nucleus represents an effective mechanism for insulin in the suppression of transcriptional activity. For example, FKHR proteins bind to *cis* elements in the promoters of the PEPCK, glucose-6-phosphatase, and IGFBP-1 genes and augment transcriptional activity. Transactivation by FKHR is prevented when cells are stimulated by insulin [241–243]. The effects on PEPCK and glucose-6-phosphatase genes have led some investigators to the conclusion that FKRH could help coordinate the overall suppression of gluconeogenesis and hepatic glucose production by insulin. However, FKHR proteins are not involved in the regulation of all genes that are suppressed by insulin. Furthermore, even in the case of PEPCK and glucose-6-phosphatase, FKHR cannot by itself account for all of transcriptional inhibition under physiologic conditions. FKHR can clearly mediate transactivation and insulin suppression of glucose-6-phosphatase and PEPCK when FKHR is overexpressed in cells; however, at physiologic levels, FKHR may not be essential for gene regulation, suggesting that other transcription factors predominate in the regulation of these two genes [243,244].

Another transcription factor, peroxisome proliferative activated receptor-γ co-activator 1 (PGC-1), was first identified as a factor involved in brown fat adipogenesis [245]. PGC-1 also plays an important role in the regulated expression of gluconeogenic enzymes, even at physiologic concentrations within hepatocytes [246,247]. In addition, PGC-1 is induced in the liver by glucagon and glucocorticoids in the context of fasting, insulin deficiency, and diabetes, and then participates in the induction of the gluconeogenic program. However, in regulating hepatic gluconeogenesis, PGC-1 may physically interact with FOXO1 and function as its co-activator [248]. In this role, FOXO1 function appears to be necessary for full induction of gluconeogenic genes by PGC-1 in hepatic cells and mouse liver. Several observations indicate that insulin may suppress gluconeogenic genes by interfering with the interaction between PGC-1 and FOXO1. For example, Akt/PKB is able to phosphorylate FOXO1, and this prevents the binding and co-activation by PGC-1. Also, insulin is able to suppress the induction of gluconeogenic genes by PGC-1 but not in the presence of a constitutively active FOXO1 mutant that is insensitive to insulin [248]. These studies indicate that a physiologic role for FOXO1 in regulating gluconeogenic gene expression may only become evident when this is examined in the context of co-activation by PGC-1.

FKHR may also play other import roles in the biology of insulin-responsive cells. FOXO1 is involved in the stimulation of pancreatic β-cell proliferation and regulation of Pdx1 expression by insulin [249]. FOXO1 also appears to contribute to the complex coordination of transcriptional events involved in adipocyte differentiation. Expression of a constitutively-active FOXO1 mutant prevents differentiation of pre-adipocytes, and

FOXO1 haploinsufficiency in mice protects from diet-induced glucose intolerance and hyperinsulinemia [250].

Sterol response element binding protein-1c (SREBP-1c)

Another exciting observation is the role of SREBP-1c in insulin-regulated gene expression. The sterol response element binding protein family of transcription factors is classically viewed as being involved in the regulation of genes in response to the cellular availability of cholesterol [251]. This family includes SREBP-1a and SREBP-1c, which are encoded by a single gene and differ only in their first exon through use of alternative transcription start sites, and the homologous SREBP-2 encoded by a second gene [252]. Evidence has accumulated that SREBP-1c is regulated primarily by insulin rather than cholesterol availability, and is also involved in adipocyte differentiation which explains the factor's alternative designation as adipocyte determination and differentiation factor-1 (ADD1) [253]. SREBP-1c/ADD1 is most highly expressed in liver, white adipose tissue, muscle, adrenal gland, and brain.

SREBPs contain an NH2-terminal domain consisting of a basic helix-loop-helix leucine zipper transcription factor, a central domain comprised of two transmembrane-spanning regions, and a COOH-terminal regulatory domain. In this form, SREBPs are associated with membranes in the endoplasmic reticulum. When membrane cholesterol concentrations are decreased, SREBP-1a and SREBP-2 undergo two sequential proteolytic cleavages, releasing the transcriptional domain, and allowing for its translocation into the nucleus [254]. These transcription factors then bind sterol responsive elements (SREs) in specific gene promoters and induce genes involved in cholesterol biosynthesis (i.e., HMG-CoA reductase, HMG-CoA synthase) and the LDL receptor, resulting in the cellular replenishment of cholesterol. Primarily regulation of SREBP-1c by insulin was first manifested in livers of fasted rodents re-fed with a high carbohydrate diet [255–257]. Subsequently, insulin was demonstrated to stimulate the expression and transcription of SREBP-1c in cell lines and in adipose, liver, and muscle tissues. This insulin effect is mediated through IRS-1 and PI-3 kinase, and possibly Akt/PKB [258], although downstream targets and transcription factors mediating induction of SREBP-1c gene transcription have not been elucidated. Regardless, SREBP-1c appears to play an important role in the regulation of specific genes in response to insulin. In experiments involving over-expression of wild-type, constitutively active, and dominant interfering mutants, SREBP-1c has been shown to be involved in the induction of fatty acid synthase and leptin in adipose cells, and glucokinase, pyruvate kinase, fatty acid synthase, and acetyl-CoA carboxylase in the liver [259]. Thus, SREBP-1c mediates a positive transcriptional effect on genes promoting glycolysis and lipogenesis, and seems to prepare the liver for carbohydrate availability following a meal. While containing SREs in their promoter regions, the above-mentioned genes are regulated by multiple hormones as well as metabolic substrates, and the relative contribution of SREBP-1c in overall transactivation by insulin has not been defined.

Signal transducer and activator of transcription 5B (STAT5B)

As discussed earlier in relationship to SOCS-3, the insulin receptor directly activates the STAT5B transcription factor via tyrosine phosphorylation [41]. STAT5B binds phosphotyrosine 972 of the insulin receptor, which is the same juxtamembrane phosphotyrosine involved in IRS binding via their PTB domains. Binding of STAT5B is the result of a SH2 domain interaction as opposed to the NPXpY-consensus sequence characterizing PTB domain interactions. Direct tyrosine phosphorylation of STAT5B by the insulin receptor kinase allows for dimerization through SH2 domain interactions and translocation into the nucleus [260,261]. This is in contrast to the general mechanism of STAT factor activation by cytokine receptors, which employs JaK kinase as the activating kinase. The complement of genes regulated through insulin activation of STAT5B has not been extensively studied. However, both glucokinase and SOCS-3 genes have STAT5 binding sites in their promoter regions, and transcriptional activity is stimulated by insulin via STAT5B [41,261].

Regulation of glucose metabolism in liver

Shawn C. Burgess

Division of Metabolic Mechanisms of Disease and Department of Pharmacology, University of Texas Southwestern Medical Center, Dallas, TX, USA

Key points

- Liver produces and consumes glucose.
- Hepatic glucose production is comprised of glycogenolysis and gluconeogenesis.
- Hepatic glucose utilization replenishes glycogen and provides substrate for lipogenesis.
- Hepatic glucose metabolism is regulated by both transcriptional and metabolic mechanisms.

Introduction

The liver regulates nutrient supply to the entire body. Antoine Lavoisier first scientifically disputed the concept of vitalism by proving that the combustion of material in the blood formed the basis of life and mechanical work by muscle. He suggested that these nutrients were not only absorbed by digestion but that liver played an important anabolic role in maintaining life [2]. Less than a century later, Claude Bernard observed that blood glucose persists in the absence of food, and that it is produced by liver from a substance that he called glycogen. Others pointed out that glucose is continuously supplied to the vessels of even the fasted (glycogen depleted) liver, which may have been the earliest detection of gluconeogenesis. Based on lower glucose in the venous blood of muscle, Bernard proposed that glucose was one of the combustible nutrients suggested by Lavoisier's experiments [3]. The next generation of scientists, such as Carl and Gerty Cori and others proved that lactate and other metabolites produced by glucose metabolism in muscle could be used as substrates to replenish glucose in liver. The cycle wherein glucose

---

[1] This chapter is an update of the same chapter in the 3rd edition of the *International Textbook of Diabetes*. The author is grateful to Christopher B. Newgard for his generous permission to retain certain excerpts of text from the previous edition [1].

is used by peripheral tissue for glycolysis and the resultant lactate is cleared by liver to resynthesize glucose is known as the Cori cycle.

Hepatic glucose synthesis, storage, and release are under the elegant control of hormone signaling networks unimaginable to early investigators. The discovery of insulin as a critical pancreatic hormone regulating glucose metabolism, and its lack as the cause of type 1 diabetes ranks among the most important medical breakthroughs of the twentieth century. Banting, Macleod and colleagues were awarded the Nobel prize in 1922, only a year after they discovered that pancreatic insulin extracts prevented death in type 1 diabetics [4]. Counterregulatory hormones, including glucagon, epinephrine, and certain glucocorticoids, which counter the actions of insulin by stimulating hepatic glucose production were discovered soon after. A major advance in understanding the mechanism of hormone action came in 1948 when Sutherland and coworkers demonstrated the existence of a glucagon-sensitive "glycogenolytic cascade" of kinase reactions which activates glycogen phosphorylase and controls the release of glucose from liver [5]. In a span of 150 years, vitalism was replaced by metabolism and the liver was identified as the source of a life-sustaining carbohydrate.

During the last century our understanding of hepatic carbohydrate metabolism grew exponentially, and broadened to include roles in lipid metabolism. The exact biochemistry of gluconeogenesis, the process that converts simple substrates into glucose, was defined. The complexities by which the gluconeogenesis is regulated are still being sorted out by researchers today. In addition, the duality of liver metabolism, embodied by its ability to both make glucose and oxidize lipid during fasting, but consume glucose and synthesize lipid upon feeding became a unique and defining feature of liver physiology. This fed-to-fasted transition is marshaled by the actions of insulin, glucagon, and other counterregulatory hormones. At the molecular level, the structure and function of enzymes involved in glucose metabolism

---

revealed fundamental mechanisms of metabolic regulation, such as phosphorylation and allosteric modifications that proved to be generalizable to all of biology.

The development of modern molecular and genetic tools has unveiled cell signaling pathways that link the regulation of hepatic glucose metabolism hormone mediated transcription and activity of specific enzymes. The dissection of molecular pathways using mouse genetics has revealed unexpected results and new paradigms of regulation. The traditional molecular physiology of liver, once explained by the adversarial influences of insulin and glucagon, is joined by a host of new hormones, transcription factors, nuclear receptors, and energy sensors. The growing complexity of our understanding of liver metabolism continues to stimulate partnerships between molecular biology, physiology, and flux/metabolomics based approaches in the hope is that these contemporary approaches will reveal a unified understanding of liver metabolism and its regulation.

Many diseases disrupt hepatic glucose metabolism, but none impact modern society more than diabetes. Caused by insulin insufficiency (type 1 diabetes) or insulin resistance (type 2 diabetes), elevated blood glucose is the hallmark of these diseases. The lack or ineffectiveness of insulin and the prevailing actions of counterregulatory hormones like glucagon cause the simultaneous overproduction and impaired disposal of glucose by the liver (Figure 13.1). Thus, following sugar ingestion, poorly controlled type 1 diabetics are unable to suppress hepatic glucose production, have impaired glucose uptake and rapidly develop hyperglycemia. In addition the total loss of insulin

and ablation of glucose catabolism potently activates hepatic fat catabolism and induces excessive ketone production and ketoacidosis that can be fatal in untreated type 1 diabetes. In type 2 diabetes, insulin levels and action are partially retained but defects of hepatic glucose production and uptake persist. Despite impaired insulin signaling to pathways which suppress glucose production, tangential signaling pathways continue to stimulate the conversion of glucose to lipid and cholesterol — a so-called "insulin paradox." This residual insulin action and other emerging mechanisms promote dyslipidemia as a significant feature of insulin resistance. Thus, both forms of diabetes cause elevated hepatic glucose production and impaired glucose uptake, but impinge differently on the way hepatic glucose and lipid metabolism interact.

The important role of dysregulated hepatic glucose balance in the pathology of diabetes has motivated more than a century of research into the fundamental regulatory mechanisms of liver glucose metabolism. Over the past decade, modern tools of molecular biology, genetics, biochemistry, physiology, and metabolomics/flux have provided a vast amount of insight into regulatory mechanisms of hepatic glucose metabolism. This chapter is an extension of the third edition of the *International Textbook of Diabetes Mellitus* [1] and devoted to integrating this new information with classic knowledge of regulatory paradigms of glucose metabolism in liver.

Hepatic glucose production

Overview
Typical lean humans spend more than half of their lives in the post-absorptive state, with less than 5 g of glucose circulating in their blood to support life [6]. Many tissues rely on glucose as their primary fuel source. Notable examples are brain, which has limited access to fatty acids, and erythrocytes which do not possess mitochondria and, therefore, rely on glycolysis to meet energy requirements. Even during rest the body uses roughly 8 g of glucose per hour, and during exercise this rate can increase more than twofold. The body would deplete circulating glucose in less than 30 min, resulting in severe hypoglycemia, loss of neurologic function and death, if not for a constant endogenous supply of glucose. Under most conditions, liver provides approximately 90–95% of circulating glucose. This hepatic glucose production is maintained at precisely the same rate as whole body glucose utilization, keeping blood glucose between 80–100 mg dL^{-1} regardless of nutritional state or activity level.

Hepatic glucose production is supplied by the breakdown of stored glycogen (glycogenolysis) and the synthesis of new glucose from noncarbohydrate precursors (gluconeogenesis). In humans, glycogenolysis and gluconeogenesis contribute about equally to hepatic glucose production following an overnight fast [7]. After 48 hours of fasting, glycogen is depleted and glucose is produced almost exclusively by gluconeogenesis [7].
Figure 13.1 Carbohydrate metabolism in the liver regulates blood glucose concentration. During fasting, the liver produces glucose at a rate that matches peripheral glucose utilization. After an overnight fast in humans (or 6-h fast in mice), glycogenolysis and gluconeogenesis contribute equally to hepatic glucose production. As fasting is extended, glycogen stores are depleted and gluconeogenesis becomes a greater contributor to glucose production.

Inasmuch as most mechanistic studies referenced in this chapter have been carried out in rodent models, it is important to note that rats and mice deplete hepatic glycogen much faster, over approximately 24 and 12 h, respectively. Gluconeogenesis and glycogenolysis are regulated by hormone action and autonomic mechanisms that alter substrate supply, allostery, posttranslational modification and enzyme transcription. These regulatory mechanisms are disrupted during type 1 and 2 diabetes leading to an inability to suppress gluconeogenesis and/or glycogenolysis and the development of hyperglycemia.

The metabolic mechanism of hyperglycemia during diabetes is one of the most widely studied pathologic features of any disease. Hyperglycemia (>124 mg dL^{-1} glucose) occurs when the equilibrium between hepatic glucose production and peripheral glucose utilization is disrupted. Either impaired glucose utilization or elevated hepatic glucose production can cause hyperglycemia (Figure 13.1). Many but not all studies find endogenous glucose production to be increased during type 2 diabetes. Perhaps more pertinent for type 2 diabetes is the failure of hyperinsulinemia to suppress hepatic glucose production, which is indicative of hepatic insulin resistance, particularly with regard to glucose metabolism [8]. Hepatic insulin resistance can be quantified using hyperinsulinemic-euglycemic clamp approaches [8]. Exogenous insulin is administered to achieve hyperinsulinemia while glucose is simultaneously infused to maintain normoglycemia. The rate of glucose infusion required to maintain normoglycemia reflects both insulin mediated glucose disposal and suppression of hepatic glucose production. If an isotope tracer of glucose is co-infused, the rate of glucose appearance can be determined from the dilution of the tracer [8]. Type 2 diabetic humans have an impaired ability to suppress both hepatic gluconeogenesis and glycogenolysis [9] in response to insulin, and this revelation has led to extensive efforts to understand the metabolic, hormonal, and transcriptional regulation of these pathways using genetically malleable models such as mice.

Glycogenolysis

Hepatocytes store glucose as polymeric units called glycogen. Fully formed glycogen particles contain thousands of glucose molecules, and can have a molecular mass in excess of 1×10^6 Da. Glycogen synthesis is an important mechanism of hepatic glucose disposal during feeding, and will be discussed later. Glycogen degradation, or glycogenolysis, converts stored glycogen into glucose during fasting. This process is initiated by removal of glucose residues one at a time from the outer, nonreducing termini of the glycogen particle. Glycogenolysis is catalyzed by the active form of glycogen phosphorylase (phosphorylase a). This enzyme catalyzes phosphorolytic cleavage of the α-1,4-glycosidic bonds of the glucose polymer to yield glucose-1-phosphate. Glucose-1-phosphate is then converted to glucose-6-phosphate by phosphoglucomutase. The G6P that is formed from glycogenolysis is hydrolyzed to free glucose via the G6Pase complex, and then transported into the circulation by GLUT2 and other emergent mechanisms. The glycogenolytic cascade is activated in liver in the fasting state by a falling insulin concentration and rising glucagon concentration. The former reduces glycogen synthesis and the latter induces glycogenolysis (Figure 13.2). However, the switch between the two conditions may not be instantaneous or complete, so glycogen synthesis and degradation can occur simultaneously. This phenomenon is called "glycogen cycling" and is most often observed in the postprandial state or hyperglycemic state [10]. Glycogenolysis is essential for maintaining glucose supply to the brain and the central nervous system during early stages of fasting, ostensibly as a buffer until counterregulatory mechanisms fully activate
Figure 13.2 Glycogen metabolism is regulated by the reciprocal actions of glycogen synthase and glycogen phosphorylase. Glycogenolysis is catalyzed by glycogen phosphorylase, which is positively regulated by glucagon-mediated phosphorylation and negatively regulated by allosteric interactions with glucose-6-phosphate. Glycogen synthesis is catalyzed by glycogen synthase, which is positively regulated by insulin and allosteric interaction with glucose-6-phosphate. The competing activity of these opposing reactions determines whether glycogen is synthesized or degraded to glucose.

gluconeogenesis. The human liver contains about 100 g of glucose as glycogen, which it depletes over about 48 hours of continuous fasting [11].

Regulation of glycogenolysis

Glycogen metabolism is regulated by reciprocal changes in the activities of glycogen synthase and glycogen phosphorylase (Figure 13.2). Net glucose production from glycogen occurs when phosphorylase activity is higher than synthase activity. Activation of glycogen phosphorylase is the culmination of a "glycogenolytic cascade" that is initiated by the binding of glucagon or β-adrenergic agonists to their receptors in liver cells [5]. The release of these hormones is stimulated by stressors such as fasting and exercise that require increased glycogenolysis to maintain glycemia. Upon activation of their hepatocyte G-protein coupled receptors, and coordinated activation of adenylate cyclase by the Ges heterotrimeric GTP-binding protein, glucagon causes a rapid rise in intracellular cAMP concentrations. This molecule causes the activation of cAMP-dependent protein kinase (PKA), which in turn leads to phosphorylation and activation of phosphorylase kinase. Finally, phosphorylase kinase phosphorylates glycogen phosphorylase, thereby converting the enzyme from its inactive (phosphorylase b) to its active (phosphorylase a) form (Figure 13.2) [12].

Similar to glycogen phosphorylase, glycogen synthase is phosphorylated under fasting conditions. However, unlike phosphorylase, phosphorylation of glycogen synthase occurs at multiple serine sites and inactivates rather than activates the enzyme [12]. Phosphorylation of glycogen synthase is catalyzed primarily by PKA and glycogen synthase kinase 3 (GSK3). In sum, a net activation of glycogenolysis is promoted during fasted or insulinopenic conditions via phosphorylation of glycogen phosphorylase and glycogen synthase, leading to activation of the former and decreased activity of the latter (Figure 13.2).

While glycogenolysis is promoted by phosphorylation of glycogen synthase and glycogen phosphorylase, a critical regulatory event for stimulating glycogen synthesis during feeding is to dephosphorylate these enzymes. The reciprocal regulation of glycogen synthase with phosphorylase and its overall participation in regulating glycogenolysis requires some consideration in our discussion of hepatic glucose production, although a more complete discussion of its role in glycogen synthesis and glucose disposal will be discussed later. A common protein phosphatase, protein phosphatase 1 (PP-1), is used to dephosphorylate both glycogen synthase and glycogen phosphorylase. The dephosphorylation mechanism is complemented by several other regulatory events. G6P binds to glycogen synthase, causing a conformational change that renders it a better substrate for PP-1. Similarly, glucose binds to glycogen phosphorylase a, again causing a conformational change that enhances its rate of PP-1-mediated dephosphorylation and decreases enzyme activity [12]. The expression of the glucose transporter GLUT2 and the glucose phosphorylating enzyme glucokinase in liver allows the levels of free glucose and G6P to rise in proportion to changes in circulating glucose concentrations, contributing to effective regulation of glycogen phosphorylase and glycogen synthase activities. In addition, the rise in insulin levels in the postprandial state activates a branch of the insulin signaling pathway that includes PI-3 kinase and Akt (protein kinase B) and stimulates phosphorylation and inhibition of glycogen synthase kinase 3 (GSK-3) [12], and other poorly understood mechanisms [13]. This results in less GSK-3-mediated phosphorylation of glycogen synthase, leaving the enzyme in a less phosphorylated, and therefore more active condition. The ability of glycogenolytic flux to be altered rapidly is an essential first response to ingestion of carbohydrate or upregulation of gluconeogenesis.

The common use of PP-1 for dephosphorylation of both glycogen synthase and glycogen phosphorylase is not a coincident, and is an example of spatial organization in the regulation of hepatic carbohydrate metabolism. It is now appreciated that enzymes of glycogen metabolism, including the regulatory enzyme PP-1, are assembled in a multiprotein complex that is also associated with the glycogen particle. This spatial association also contributes to appropriate activation or suppression of glycogen synthesis in response to changes in nutritional conditions. The scaffolding proteins that organize glycogen metabolism are known collectively as glycogen-targeting subunits of PP-1 [12].

In principle, glycogen synthesis and glycogenolysis are reciprocally regulated by the antithetic control of glycogen synthase and glycogen phosphorylase (as discussed earlier). It should be noted, however, that this reciprocal regulation may not always be complete. Thus, in controlled experimental circumstances, such as during hyperinsulinemic-euglycemic clamp protocols in humans, a decrease in net hepatic glycogenolysis can be demonstrated, which is due to a large activation of glycogen synthase flux, but without a decrease in phosphorylase flux [14]. Thus, glycogenolysis can continue during periods of net glycogen synthesis, suggesting that a significant portion of the phosphorylated glucose derived from glycogenolysis in liver can be recycled back into glycogen (i.e., glycogen cycling). Thus, control of liver glycogen metabolism should not be viewed simply as regulation of perfectly reciprocal "on" and "off" switches, but more as control of net flux via a predominance of activity of one pathway relative to the other.

Gluconeogenesis
Gluconeogenic pathways

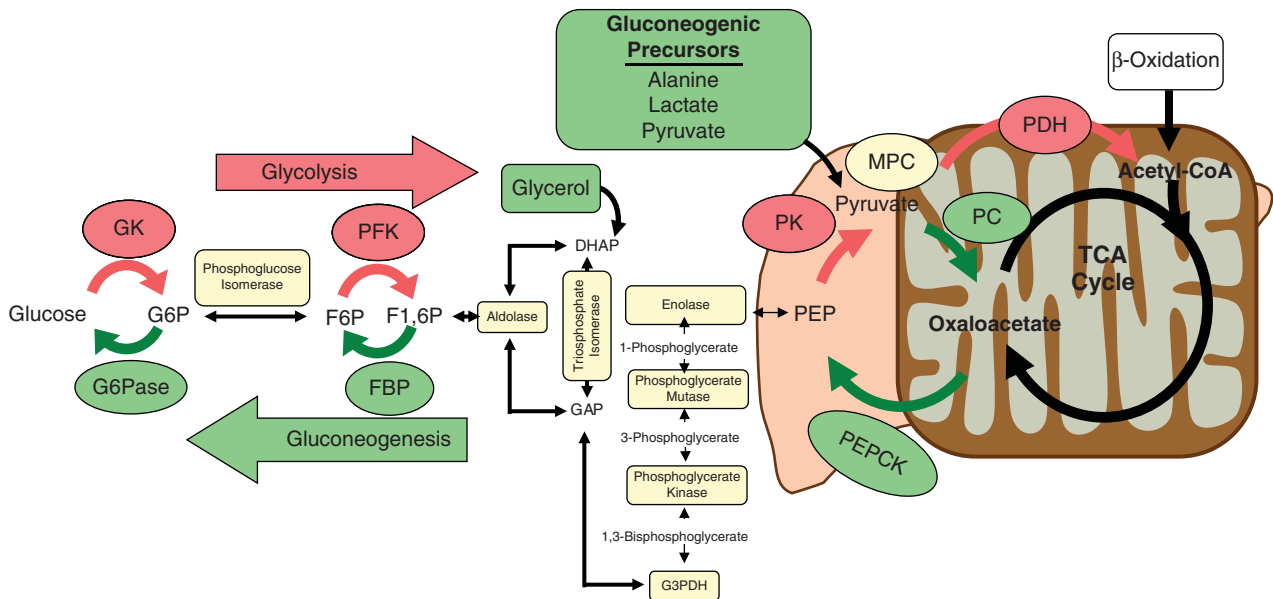
Gluconeogenesis is the synthesis of glucose from three carbon precursors such as alanine, pyruvate, lactate, and glycerol and is essentially a reversal of glycolysis [15] (Figure 13.3). Under normal conditions, 90% of gluconeogenesis occurs in liver, and the rest occurs mainly in the renal cortex. Other sites of gluconeogenesis, such as the small intestine have been suggested but remain controversial. Estimates of gluconeogenesis have


Figure 13.3 Gluconeogenesis and glycogenolysis are opposing pathways but share a majority of their enzymes. However, several steps are functionally irreversible and require separate enzymes. Glucokinase (GK) and glucose-6-phosphatase catalyze the opposing phosphorylation and de-phosphorylation of glucose. Phosphofructokinase (PFK) and fructose-1,6-bisphosphatase (FBP) catalyze the phosphorylation and de-phosphorylation of fructose-6-phosphate. The conversion of phosphoenolpyruvate (PEP) to pyruvate is catalyzed by L-pyruvate kinase (PK), but requires additional steps to synthesize PEP from pyruvate. Pyruvate must be transported into the mitochondria by the mitochondrial pyruvate carrier (MPC), is then converted to oxaloacetate by pyruvate carboxylase (PC), and transported back to the cytosol where it is converted to PEP by phosphoenolpyruvate carboxykinase (PEPCK). The opposing enzyme steps are important points of transcriptional and posttranscriptional control of gluconeogenesis.

been based on either arterio-venous differences across the splanchnic bed, magnetic resonance measurements of hepatic glycogen depletion during fasting, or a variety of isotope tracer methodologies. In humans, gluconeogenesis contributes 40–50% of endogenous glucose production after an overnight fast, though this number varies depending on the method used [16]. During continued fasting, endogenous glucose production remains constant because gluconeogenesis rises in proportion to compensate for glycogen depletion. After about 48 hours of fasting in humans, all glucose is produced by gluconeogenesis. This is roughly the same timing at which people enter ketosis, a metabolic adaptation of liver to produce ketones from lipids and supplement glucose utilization in peripheral tissue. During extended fasting, total glucose production decreases as low insulin levels suppress peripheral glucose utilization, hepatic glycogen is depleted and the body adapts to ketone and lipid oxidation.

Gluconeogenic substrates

Most amino acids, organic acids and glycerol can be substrates for hepatic gluconeogenesis. Notably, liver lacks the enzymes to convert acetyl-CoA to glucose, thus even chain fatty acids, ketones and certain ketogenic amino acids cannot be used as gluconeogenic substrates, although mixing of carbon pools in the TCA cycle does occur [16] (Figure 13.3). Lactate and alanine are key components of the Cori cycle, the process by which glycolysis in peripheral tissue produces these intermediates

and the circulation delivers them to the liver where they are converted to pyruvate and used to resynthesize glucose. Glycerol is produced by lipolysis in adipose tissue during fasting, and in humans contributes to about 10% of glucose production after an overnight fast, but increases during starvation and in diabetes [17,18]. Glycerol is distinct from other gluconeogenic precursors because it is technically already an alditol (e.g. sugar alcohol) and requires less free energy to be converted to glucose. Glycerol is converted to the gluconeogenic intermediate dihydroxyacetone phosphate by the combined actions of glycerol kinase and glycerol phosphate dehydrogenase, and thus bypasses several regulatory steps discussed later. All other gluconeogenic precursors must pass through mitochondrial pathways and their conversion to glucose is generally endergonic (Figure 13.3).

Gluconeogenic enzymes

A minimum of 11 enzymatic steps are required to convert two molecules of pyruvate to one molecule of glucose [15]. Seven of these enzymes catalyze reversible reactions of glycolysis such as aldolase and triose phosphate isomerase. Another four reactions are catalyzed by unique enzymes which circumvent irreversible steps of glycolysis (Figure 13.3). Gluconeogenesis from pyruvate begins with the transport of pyruvate into the mitochondria via the mitochondrial pyruvate carrier (MPC). Once in the mitochondria pyruvate is converted to oxaloacetate, by the mitochondrial enzyme pyruvate carboxylase (PC).

Oxaloacetate is then decarboxylated by phosphoenolpyruvate carboxykinase (PEPCK) to yield the glycolytic intermediate phosphoenolpyruvate (PEP). There are two isoforms of PEPCK, a cytosolic isoform (PEPCK-C) and a mitochondrial isoform (PEPCK-M). The human liver expresses about 50% of each, but the mouse liver expresses roughly 95% of its PEPCK as the cytosolic isoform [19]. Studies in genetically engineered mice indicate that the cytosolic isoform is most important for gluconeogenesis [20].

Since mitochondria do not possess an oxaloacetate transporter, a modified malate-aspartate shuttle is utilized to transport substrates from mitochondria to the cytosol where PEPCK-C and other gluconeogenic enzymes are located. The exact form of this shuttle depends on cytosolic redox state. In its simplest form, mitochondrial oxaloacetate is reduced to malate by mitochondrial malate dehydrogenase with the oxidation NADH to NAD$^+$. Malate is transported out of the mitochondria in exchange for inorganic phosphate and then oxidized by cytosolic malate dehydrogenase to generate oxaloacetate and an NADH. Thus this pathway predominates when oxidized gluconeogenic substrates like pyruvate or alanine are utilized. Alternatively, mitochondrial oxaloacetate can be transaminated to aspartate and transported to the cytosol in exchange for glutamate, and then transaminated back to oxaloacetate. Although this process requires additional steps for transamination, it allows oxaloacetate to be transported in a redox neutral fashion (i.e., no net transport of NADH to the cytosol). The transaminase-dependent shuttle is critical for reduced substrates like lactate, but is not required for pyruvate itself.

Cytosolic phosphoenolpyruvate is converted to fructose-1,6-bisphosphate via six enzymatic steps common to glycolysis. However, conversion of fructose-1,6-bisphosphate to fructose-6-phosphate requires a distinct enzyme, fructose-1,6-bisphosphatase, as the ATP-consuming phosphofructokinase reaction of glycolysis is not reversible. Fructose-6-phosphate is then converted to glucose-6-phosphate by reversal of the hexose phosphate isomerase reaction of glycolysis. The terminal step of gluconeogenesis is the hydrolysis of glucose-6-phosphate (G6P) to free glucose, catalyzed by the glucose-6-phosphatase (G6Pase) enzyme complex. The complex is comprised of a catalytic subunit sequestered within the endoplasmic reticulum (ER), a glucose-6-phosphate translocase known as T1 that delivers glucose-6-phosphate to the catalytic subunit, and putative ER glucose and inorganic phosphate transporters (T2, T3) that move the reaction products back into the cytosol. The sequestration of G6Pase in the ER may protect other phosphorylated sugars from the nonspecific phosphohydrolase activity of its catalytic subunit. Specificity of the system is conferred by the T1 translocase component, which transports glucose-6-phosphate, but not its closely related epimer mannose-6-phosphate. This prevents uncontrolled hydrolysis of phosphorylated sugars and spares energy.

Transcriptional regulation of gluconeogenesis

The gradual shift from the fed-to-fasted state is followed closely by hormonal regulation of genes encoding PEPCK, fructose-1,6-bisphosphatase, and the glucose-6-phosphtase catalytic subunit. The transcriptional regulation of these genes remains a developing research area and its many emerging nuances cannot be completely covered here. However, this regulation is accomplished largely through two transcription factors, CREB and FOXO, the nuclear receptors GR, HNF-4α, and the coactivator PGC-1α [21,22] (Figure 13.4). Classic glucoregulatory hormones such as insulin, glucagon, and glucocorticoids mediate gluconeogenic gene expression by promoting or inhibiting the interaction of these proteins with the promoter regions of these genes [23]. More recently described hormones such as adiponectin, and posttranslational mediators of hepatocyte energy status like AMPK [24] and surtuins also act on these transcriptional regulators to influence glucose metabolism in liver, and are discussed later.

Induction of gluconeogenic gene expression

Fasting causes increased levels and stability of PEPCK mRNA [25,26]. The PEPCK gene promoter contains binding sites for more than a dozen transcription factors, nuclear receptors and co-regulators. This allows the promoter to be exquisitely responsive to nutrition and stress. The best-studied factors regulating PEPCK expression are its activation by glucagon and glucocorticoids, and its inhibition by insulin [25,26] (Figure 13.4). Glucagon activates its G-protein coupled receptor on the cell surface of hepatocytes and stimulates cyclic AMP (cAMP) production. cAMP binds protein kinase A (PKA) and activates its kinase domain. After diffusion into the nucleus, PKA phosphorylates Ser133 of the cAMP-response element binding protein (CREB). CREB then binds to the cyclic AMP response element (CRE) in the PEPCK and G6Pase gene promoters [27]. Binding of phosphorylated CREB to its CRE site nucleates the assembly of its co-activator, the CREB binding protein (CBP), and initiates transcription. The stability of this complex is modulated through phosphorylation of the interacting domains by several kinases, including Ca^{2+}/calmodulin-dependent kinases [21].

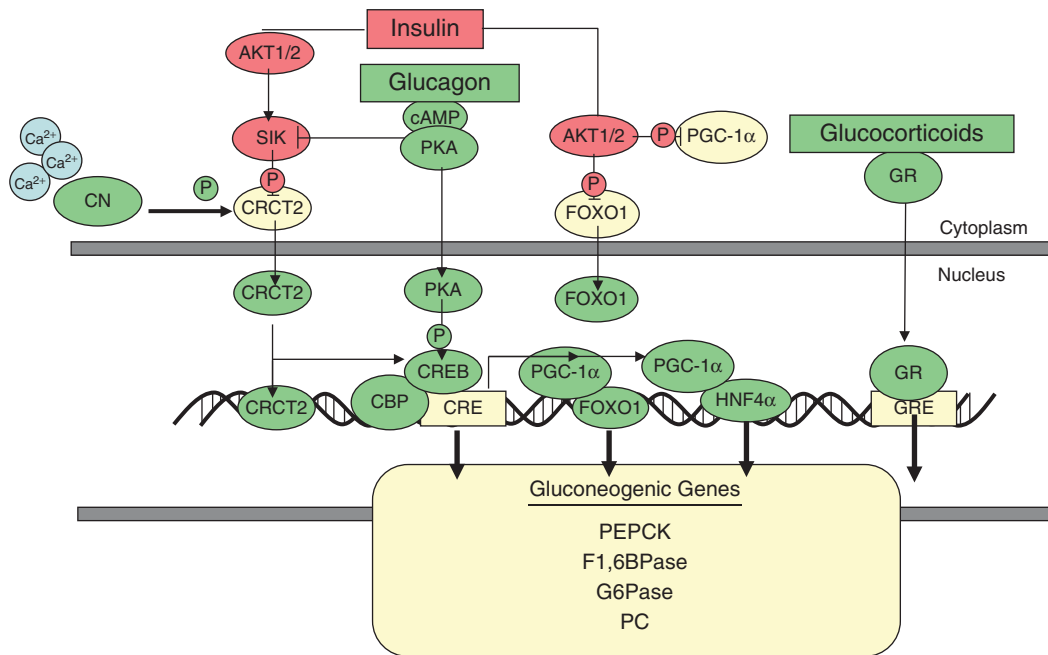
Transcription by CREB is also robustly potentiated by a second co-activator, cAMP-regulated transcriptional co-activator (CRTC2, or TORC2) (Figure 13.4). CRTC2 is maintained inactive by salt inducible kinases (SIK) which phosphorylate and sequester CRTC2 in the cytoplasm [21]. In addition to activating CREB, PKA also inhibits SIK, while other phosphatases, including calcineurin (a Ca2+/calmodulin-dependent phosphatase) dephosphorylate CRTC2. Dephosphorylated CRTC2 is then translocated into the nuclease and promotes transcription of CREB targets [21]. In addition to gluconeogenic genes, CREB also initiates the expression of other positive regulators of gluconeogenesis such as PGC-1a and NR4A, a nuclear receptor that also induces gluconeogenic gene expression. Thus, glucagon is a powerful impetus for regulating gluconeogenic


Figure 13.4 Transcriptional regulation of gluconeogenesis. Insulin and counterregulatory hormones instigate transcriptional events that modify the expression of key gluconeogenic enzymes. Glucagon mediates nuclear PKA activity which phosphorylates CREB, stabilizes the CRE complex and induces gluconeogenic enzyme expression. Insulin opposes gluconeogenic enzyme expression by signaling the phosphorylation of CRCT2 and FOXO1 which are then excluded from the nucleus and unable to induce gluconeogenic enzyme expression. Other factors such as glucocorticoids also have nuclear receptors that induce expression of gluconeogenic enzymes.

gene expression in liver, but its complexity also allows for its actions to be moderated or magnified by other factors, as we will see later. Employing a similar paradigm, glucocorticoids bind to the cytosolic glucocorticoid receptor (GR) causing its dissociation from a chaperone protein and its translocation to the nucleus where it binds to a glucocorticoid response element (GRE) in the PEPCK promoter (Figure 13.4). Formation of the GR/GRE complex leads to recruitment of other proteins (albeit it different ones from those bound to the CREB/CRE complex), again leading to stimulation of PEPCK gene transcription.

Repression of gluconeogenic gene expression
Insulin represses glucagon and glucocorticoid induction of gluconeogenic gene expression through incompletely understood mechanisms that may be partially permissive in nature [28] (Figure 13.4). In contrast to glucagon action, which facilitates the binding of CREB to its promoters, insulin signaling excludes the forkhead transcription factor (FOXO1) from the nucleus and prohibits its binding to the promoters of PEPCK and G6pase [23]. Mouse studies in which insulin signaling and FOXO1 are acutely deleted have demonstrated that the upregulation of gluconeogenic genes during loss of insulin action requires FOXO1 [28,29]. Binding of insulin to its receptor initiates phosphorylation of the insulin receptor substrates and PI3Kinase. These events trigger a broader phosphorylation cascade which mediates the metabolic effect of insulin. Akt1/2, also known as protein kinase B, is activated by PI3Kinase and

is required for most of insulin's actions on lipid and glucose metabolism [22]. Akt1/2 (mainly Akt2 in the normal mouse liver) acts on gluconeogenesis by phosphorylating FOXO1, which is then excluded from the nucleus, causing gluconeogenic genes to be repressed [22]. Notably, Akt1/2 also phosphorylate and deactivate proteins required for glucagon action such as SIK and PGC-1α (see later), and activates proteins required for lipogenesis [23].

Role of PGC-1α
PGC-1α is a co-activator that binds to multiple transcription factors and nuclear receptors during fasting and/or the energy challenged state [30]. Like other coactivators, PGC-1α acts on nuclear chromatin to facilitate the binding transcription factors to target genes. Although very low in liver of fed mice, PGC-1α increases dramatically in liver during fasting [31]. The full induction of gluconeogenesis requires functioning PGC-1α and several models of type 1 and type 2 diabetes have increased expression or activity of hepatic PGC-1α [32]. PGC-1α is activated in response to cAMP and CREB and is thus an important component of counterregulatory hormone signaling. Once expressed, PGC-1α activity is modified posttranslationally by phosphorylation and acetylation under the regulation of AMPK and sirtuins (see later). Active PGC-1α induces the gluconeogenic enzymes, PEPCK, fructose-1,6-bisphosphatase, and the catalytic subunit of the G6Pase complex by co-activating hepatocyte nuclear factor 4-α and FOXO1 [31] (Figure 13.4).

PGC-1α also mediates fat oxidation in liver during fasting by co-activating PPARα. The induction of energy production by PGC-1α is essential to support the energetic expense of gluconeogenesis during fasting and is an additional route of gluconeogenic control by PGC-1α [32].

In summary, the regulation of gluconeogenic gene expression is carried out by a rise in cAMP levels caused by counterregulatory hormones during fasting or exercise. These hormones activate CREB, increase PGC-1α expression and stimulate expression of gluconeogenic genes via FOXO1 and HNF4α. Their effects are antagonized by insulin in the fed state via Akt1-mediated phosphorylation of FOXO1, resulting in suppression of gluconeogenic gene expression.

Acute regulation of gluconeogenesis

Prior to discovery of the transcriptional mechanisms described earlier, the control of hepatic glucose metabolism was examined in great detail on the basis of substrate, allosteric, and posttranslational modification. These factors alter gluconeogenic flux rapidly (seconds to minutes) and are a critical first response to increased glucose demand. Much of the acute regulation of gluconeogenesis is based on the antithetic regulation of several gluconeogenic/glycolytic enzyme pairs that catalyze opposing pathways. The metabolic intersections of PC/PDH, PEPCK/PK, G6Pase/glucokinase and fructose-1,6-bisphosphatase/phosphofructokinase are critical sites for the regulation of gluconeogenesis. Logically, alterations that inhibit the regulatory glycolytic enzymes (PDH, GK, PFK, or PK) will promote gluconeogenesis, while alterations that inhibit regulatory gluconeogenic enzymes (PC PEPCK, G6Pase, or fructose-1,6-bisphosphatase will promote glycolysis.

Allosteric and covalent modification

Allosteric modification of enzyme activity occurs when an enzyme binds to a molecule, causing either an increase or decrease in the enzyme's activity. Allosteric binding sites are separate from the catalytic domains and interact with their effector molecules by noncovalent bonding. Typically, electrostatic or hydrogen bonding between the effector molecule and amino acid residues of the allosteric binding pocket cause a change in the quaternary structure of the protein or otherwise change the binding constant of the catalytic site of the enzyme. Importantly, the effect on conformation and activity is essentially instantaneous and independent of the transcriptional mechanisms described earlier. In contrast, covalent modification occurs when new functional groups are added to amino acids of the enzyme. The effect of covalent modification also changes the conformation and therefore the activity of the enzyme. The most common types of covalent modifications of metabolic enzymes are phosphorylation and acetylation, though many others can also occur. Covalent modification requires the activity of other proteins such as kinases and/or phosphorylases to add or cleave covalently bound functional groups.

Pyruvate dehydrogenase

Mitochondrial pyruvate can either be decarboxylated by PDH to yield acetyl-CoA (lipogenesis/oxidation) or carboxylated by PC to yield oxaloacetate (gluconeogenesis) (Figure 13.5). These divergent fates of pyruvate are influenced by nutritional state and are reciprocally regulated by allosteric and or covalent modification. PDH is part of a very large complex of proteins known as the pyruvate dehydrogenase complex (PDC). Inasmuch as glucose production is required for survival, hepatic PDH is normally kept in an inactive state by allosteric inhibition and phosphorylation. PDH activity is allosterically inhibited by acetyl-CoA, NADH, and ATP, factors that are replete in the fasted liver. PDH is also inactivated by a family of pyruvate dehydrogenase kinases (PDK) that phosphorylate PDH [33]. PDK-4 expression is decreased by insulin action, increased by counterregulatory hormones and its activity is stimulated by
Figure 13.5 Regulation of mitochondrial pyruvate flux. Mitochondrial pyruvate can be converted to acetyl-CoA by pyruvate dehydrogenase (PDH) or oxaloacetate by pyruvate carboxylase (PC). Both enzymes are metabolically regulated by cellular energy status. Acetyl-CoA, ATP, and NADH signal an energy rich hepatocyte and allosterically activate pyruvate dehydrogenase kinase-4 (PDK4), which deactivates PDH by phosphorylation. Acetyl-CoA on the other hand is a powerful allosteric activator of pyruvate carboxylase. Thus high energy states facilitate gluconeogenesis and suppress glucose oxidation and/or lipogenesis. In the overnight fasted state, PC is 10-fold more active than PDH.

acetyl-CoA, NADH, and ATP [33]. PDH activity is de-repressed during feeding, allowing glucose to be converted to acetyl-CoA for oxidation or lipogenesis (see hepatic glucose disposal later).

Pyruvate carboxylase

Suppression of PDH during starvation preserves pyruvate for pyruvate carboxylase (PC) and gluconeogenesis (Figure 13.5). PC is a mitochondrial enzyme that catalyzes the carboxylation of pyruvate to oxaloacetate and exerts more powerful control over gluconeogenesis than all of the other enzymes of the pathway combined [34]. Although its transcriptional regulation is weak, the allosteric control of PC has been thoroughly examined and provides a glimpse into the elegant regulation possible by acute metabolic feedback. In contrast to PDH, PC is allosterically activated by acetyl-CoA [35]. Thus, during fasting, when fat oxidation is increased, PC is activated and provides ample oxaloacetate for gluconeogenesis. Isotope tracer studies indicate that the *in vivo* activity of PC in the human postabsorptive liver is roughly up to 100 times higher than PDH [36,37].

The rapid regulation of PC activity by allostery is made possible by its tetrameric structure [35]. PC has two biotin domains on each face of a tetrahedral. One domain facilitates the $MgATP/HCO_3^-$ dependent carboxylation of a biotin, and the other is a transferase domain where the carboxyl group is transferred to pyruvate. Activity of the PC complex requires that the carboxylated biotin domain access the transferase domain of the adjacent monomer. Acetyl-CoA binds amino acid residues in an allosteric binding site and induces a conformation that is favorable for the interaction of these domains. In the absence of acetyl-CoA, these domains cannot interact and PC activity approaches zero. The K_a for acetyl-CoA binding is 20–60 uM, a value within the biologic range of acetyl-CoA concentration in liver mitochondria [35]. Intermediates associated with the

TCA cycle such as α-ketoglutarate and glutamate reduce the Ka for acetyl-CoA, thereby effectively inhibiting PC activity. This may provide a metabolic mechanism allowing oxaloacetate production to match TCA cycle capacity. Despite the elegant metabolic regulation of PC, its role as a rate-controlling step in gluconeogenesis has received little attention in the study of mechanism leading to the elevation of hepatic glucose production during diabetes.

Pyruvate kinase

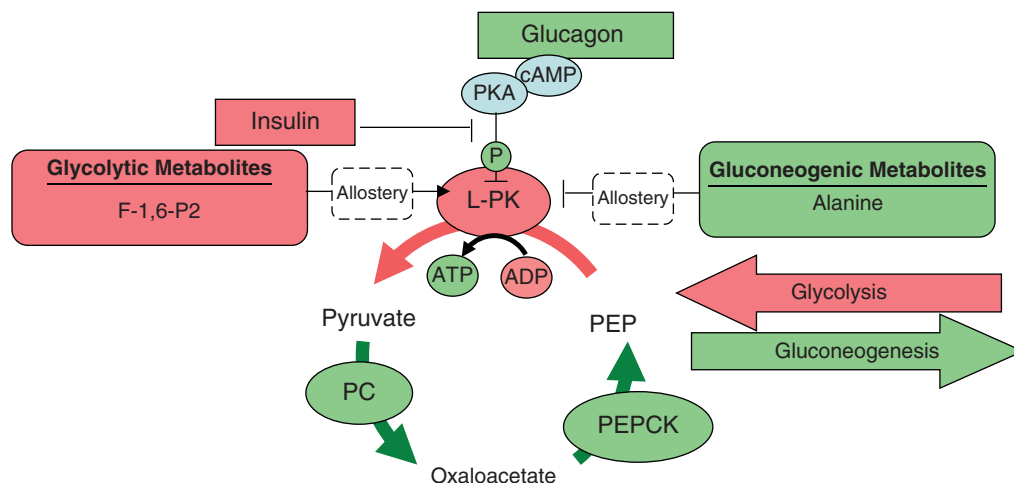
Liver pyruvate kinase (L-PK) catalyzes the irreversible conversion of PEP to pyruvate and ADP to ATP. L-PK contributes to the positive regulation of glycolysis and lipogenesis and is discussed more thoroughly in these contexts in the later section on glucose disposal. However, it is worth noting that by opposing the combined actions of PC and PEPCK, L-PK acts as an important negative regulator of gluconeogenesis [15,38]. Experimentally, the generation of pyruvate from gluconeogenic PEP is an active substrate cycle in liver (Figure 13.6). Tracer experiments in hepatocytes [39], isolated liver [40], animal models [41] and humans [37] indicate that roughly half of PC flux is cycled back to pyruvate. Collectively these pathways are referred to as pyruvate cycling, and ostensibly confer greater metabolic flexibility by directing an already active flux towards or away from gluconeogenesis on fast time scales [15]. L-PK is suppressed by glucagon (and to a lesser extent epinephrine) via cAMP-mediated PKA action and as with other examples of actions of counterregulatory hormones, insulin opposes this process. L-PK activity is also allosterically activated by F-1,6-P2 and inhibited by alanine and ATP. Phosphorylation of L-PK by PKA decreases the maximal activation of L-PK by its substrates and potentiates the effectiveness of alanine and ATP to allosterically suppress its activity. Moreover, L-PK is a better substrate for phosphorylation by


Figure 13.6 Metabolic regulation of liver pyruvate kinase. Pyruvate kinase opposes gluconeogenesis by removing PEP from the gluconeogenic pathway. Counterregulatory activation of cAMP and induction of PKA suppresses L-PK by rapid phosphorylation. Insulin promotes L-PK activity by opposing its phosphorylation and by inducing the glycolytic intermediate fructose-1,6-bisphosphate and allosteric activation of L-PK. The gluconeogenic precursor alanine has a negative allosteric effect on L-PK, consistent with a feed forward activation of gluconeogenesis. Tracer studies indicate that L-PK is constantly on and constitutes a pyruvate cycle between PC, PEPCK and L-PK, thereby conferring greater metabolic control of PEP entrance into gluconeogenesis.

PKA when it is allosterically inhibited by alanine or ATP than when it is allosterically activated by F-1,6-P2. Thus allosteric regulation not only mediates L-PK activity directly, but also deters phosphorylation of the enzyme [15].

Fructose-1,6-bisphosphatase/ phosphofructokinase

Allosteric regulation of hexose flux is another example where the regulation of gluconeogenesis occurs by interaction with glycolytic regulation. The conversion of F-1-P to F-1,6-P2 is irreversibly catalyzed by the gluconeogenic enzyme fructose-1,6-bisphosphatase, and the opposite glycolytic reaction is irreversibly catalyzed by phosphofructokinase. Like the intersection between PC-PEPCK and L-PK, fructose-1,6-bisphosphatase and PFK resemble a futile cycle but which is actually a finely tuned point of metabolic control [15]. Liver phosphofructokinase is allosterically inhibited by PEP and citrate, which are indicative of abundant energy and substrate for gluconeogenesis (Figure 13.6). More importantly, phosphofructokinase is regulated by $F-2,6-P_2$, a product of $F-1,6-P_2$ and the bifunctional enzyme. Fructose-1,6-bisphosphatase is also inhibited by $F-2,6-P_2$, the product of the bifunctional enzyme during feeding [15]. However, like most other substrate cycles discussed in this chapter, complete deactivation of the opposing fluxes of fructose-1,6-bisphosphatase and the bifunctional enzyme is not complete, even during a substrate load [42]. The regulation of the relative activities of FBPase and PFK is addressed again in the discussion of hepatic glucose disposal later.

Hepatic energetics and glucose production

Hepatic gluconeogenesis uses more than 40% of the energy consumed by the human liver [36]. Gluconeogenesis consumes 4 moles of ATP, 2 moles of GTP, and 2 moles of NADH for every mole of glucose produced. This energy is supplied in large part by the oxidation of fatty acids, which is promoted in the fasted state via a fall in the concentration of malonyl CoA and activation of carnitine palmitoyltransferase 1 (CPT 1) [43]. The allosteric and substrate effectors mentioned throughout this section (NADH/NAD+, ATP/AMP, acetyl-CoA, citrate, etc.) are products of fatty acid oxidation. Consequently, fat oxidation is required for optimal gluconeogenesis in hepatocytes and perfused liver [44]. When defects in fat oxidation occur, either due to targeted ablation in mice or inborn errors in humans, impaired gluconeogenesis and hypoglycemia almost always emerge as complications. In contrast, exogenous lipid infusion induces gluconeogenesis *in vivo* [45]. The metabolic dependence of hepatic gluconeogenesis on fat oxidation is imparted by the allosteric and covalent activation of the enzymes of gluconeogenesis and glycolysis [44] (Figure 13.7). Recall that PC activity is allosterically activated by acetyl-CoA, a product of the β-oxidation of fatty acids. Condensation of acetyl-CoA with oxaloacetate is the first step of the tricarboxylic acid (TCA) cycle and leads to the generation of citrate and NADH, and ultimately to a rise in ATP/ADP through the actions of the respiratory chain. Together, citrate, NADH and ATP, are the same factors
Figure 13.7 Hepatic energy production positively enhances gluconeogenesis. The metabolic products and cofactors downstream of oxidative metabolism are metabolic activators of gluconeogenesis. Acetyl-CoA activates PC and inhibits PDH. Citrate generated during the oxidation of acetyl-CoA is a powerful inhibitor of the glycolytic enzyme PFK and therefore an activator of gluconeogenesis. NADH and GTP generated by the TCA cycle and ATP generated by respiration are required cofactors for the gluconeogenic reactions glyceraldehyde 3-phosphate dehydrogenase (GAPDH), PEPCK, and phosphoglycerate kinase (PGK), respectively.

that suppress PFK, PK, and PDH in glycolysis. In addition, the high energy cofactors, ATP, GTP, and NADH, are consumed by the gluconeogenic enzymes, PC, PEPCK, phosphoglycerate kinase, and glyceraldehyde-3-phosphate dehydrogenase. During fasting, low insulin and high counterregulatory hormones promote adipose lipolysis, elevated circulating fatty acids, upregulation of hepatic lipid oxidation, upregulation of gluconeogenic genes, and an abundance of the cofactors required to stimulate gluconeogenesis. As fasting continues into starvation, gluconeogenic substrates become scarce, fatty acid oxidation increases and elevated mitochondrial NADH/NAD+ reduces the activity of the TCA cycle. Under these conditions acetyl-CoA is converted to ketones to supplement falling rates of hepatic glucose production.

Hepatic energetics as a therapeutic target for diabetes

Biguanides, such as metformin, have been used as antidiabetic agents for several decades and today metformin remains the first medicine prescribed to newly diagnosed type 2 diabetics. Metformin improves glycemia by suppressing hepatic gluconeogenesis, but the mechanism by which this occurs has only recently, and only partially, been uncovered. Rather than inhibiting PEPCK or other gluconeogenic enzymes directly, metformin appears to reduce the gluconeogenic potential of liver by impairing hepatic energy metabolism [46]. Metformin impairs ATP synthesis by inhibition of respiratory complex I [47] and may also reduce the hepatocellular redox state

by suppressing NADH utilization in the respiratory chain. Suppressed energy charge has secondary effects that reduce gluconeogenic gene expression through AMPK signaling [48], though this does not appear to be necessary for many of the metabolic effects of metformin [46]. A primary action on gluconeogenesis by metformin may be more metabolic in nature. By limiting energy supply, metformin inhibits high rates of gluconeogenesis, consistent with the requisite role of hepatic energy production in support of gluconeogenesis described earlier. In contrast to many other therapeutic targets of hepatic glucose metabolism, metformin has relatively few adverse effects, with rare manifestations of lactic acidosis being the most common.

Substrate supply and hepatic glucose production

The availability of gluconeogenic substrate is an important determinant of hepatic glucose production [49]. Glucagon and other hormones act on peripheral tissues to increase substrate delivery to liver. These events are particularly relevant during fasting and diabetes when a rise in the glucagon:insulin ratio causes activation of hormone-sensitive lipase and other lipases, which catalyzes the hydrolysis of triglycerides to yield free fatty acids and glycerol. The free fatty acids are transported to liver and re-esterified or oxidized. Oxidation is increased during fasting and diabetes because lower glycolytic flux in these states decreases malonyl-CoA mediated inhibition of CPT1 transport of fatty acids into mitochondria and increases the rate of fatty acid oxidation [43]. Fatty acid oxidation provides NADH and ATP required for optimal gluconeogenic activity [44]. Glucagon and glucocorticoid action also increases the supply of gluconeogenic precursors by inducing skeletal muscle autophagy, protein synthesis, and amino acid supply, while insulin has the opposite effect [50]. In addition counterregulatory hormones and fatty acids activate fat oxidation in muscle and suppress PDH activity which in turn stimulates aerobic glycolysis in the periphery. The lactate formed under these conditions is used by liver for gluconeogenesis and forms the basis of the Cori cycle. This cycle is particularly important during exercise where lactate formation in muscle provides ATP and defers the oxidative burden to liver.

The relative importance of substrate supply and hormone action on hepatic glucose production has been studied using mouse genetics and sophisticated metabolic clamps. Chronic ablation of the liver insulin receptor results in hyperglycemia [51], but acute ablation does not affect glycemia [52,53]. Specific restoration of the liver insulin receptor in mice missing the receptor in peripheral tissue is also insufficient to normalize hepatic glucose production [54]. Thus, the peripheral effects of insulin are important determinants for hepatic glucose metabolism. In canine models, where hormone and substrate can be delivered directly to liver by infusion into the portal vein, insulin action acutely suppresses hepatic glucose production by reducing glycogenolysis and directing gluconeogenic G6P to glycogen synthesis [55]. Although hepatic insulin is sufficient to mediate changes in gluconeogenic gene expression, insulin per se, does not rapidly alter gluconeogenic flux [55]. Thus, insulin action in liver is effective at regulating glycogen flux in the course of minutes, but requires hours to establish the molecular conditions to increase hepatic gluconeogenesis. In contrast, experiments where insulin was delivered to peripheral tissue, gluconeogenesis was reduced mainly by insulin-mediated suppression of adipose lipolysis and reduced delivery of free fatty acids to liver [56]. Insulin's effect on hepatic gluconeogenic gene expression and its ability to restrict substrate supply from the periphery work together to reduce gluconeogenesis.

Linking molecular and metabolic regulation of hepatic glucose metabolism

Cross-talk between metabolism and molecular biology is an emerging mechanism of metabolic regulation and is particularly relevant to the control glucose metabolism in liver. Some transcription factors and nuclear receptors are activated in response to metabolites. During fasting lipid metabolites are released that activate PPARα and induce the gene expression of oxidative metabolism. The activation of mitochondrial metabolism, as described earlier, has a positive effect on gluconeogenesis and ketogenesis [57]. In contrast, hypoxia inducible factor-1α (HIF-1α) is a transcription factor that upregulates glycolysis and suppresses mitochondrial respiration when TCA cycle intermediates (e.g. fumarate, succinate, and α-ketoglutarate) are elevated. Although most commonly related to mitochondrial dysfunction in heart disease and cancer, constitutive stabilization of hepatic HIF by loss of the von Hippel-Lindau protein results in dramatically impaired hepatic TCA cycle, respiration, blunted gluconeogenesis, hepatic steatosis, and hypoglycemic death [58]. The physiologic role of HIF in liver has not been rigorously studied. Other proteins, such as AMPK [59] and sirtuins [60], mediate the phosphorylation and acetylation of multitudes of enzymes, cell signaling proteins and transcription factors in response to cellular energy status.

AMPK

AMP activated protein kinase (AMPK) is activated in response to elevated AMP (i.e., low energy). AMPK generally activates metabolic pathways that produce cellular energy and suppresses pathways that consume energy [24,59,61]. In liver, AMPK suppresses anabolic pathways like gluconeogenesis, lipogenesis, and cholesterol synthesis [61] and activates β-oxidation *via* PGC-1α [62]. Among AMPK's most acute responses to energy demand is the rapid phosphorylation and inactivation of acetyl-CoA carboxylase (ACC) [63] resulting in lower malonyl-CoA, activated CPT1 and increased oxidative metabolism [64]. AMPK activation is exquisitely sensitive to the energetic stress of gluconeogenesis [65]. The normal induction of hepatic AMPK during fasting does not occur when gluconeogenesis is blunted [66]. Thus, among its many other functions, AMPK helps the liver match energy production to the energy demand of gluconeogenesis.

Sirtuins

Sirtuins are a class of NAD+ dependent deacetylase that regulate transcription and posttranslational activity by deacetylating key sites of numerous proteins [60]. There are 7 sirtuins in humans, with sirt1 and sirt3 playing important roles in the deacetylation of cytosolic/nuclear and mitochondrial proteins, respectively. Because of their dependence on NAD+, sirtuins are potentially redox sensitive and thus metabolically regulated. For example, the cytosolic/nuclear sirt1 upregulates gluconeogenesis by deacetylating several important regulatory factors including PGC1-α and FOXO1. However, sirt1 also suppresses CREB-mediated gluconeogenic gene expression which may reduce gluconeogenesis during starvation as ketone production predominates and gluconeogenic precursors become limited. Mitochondrial sirt3 may influence gluconeogenesis by modifying the activity of β-oxidation and the TCA cycle [67].

Hepatic glucose disposal

Overview

Carbohydrate ingestion switches liver from a net glucose producer to a net glucose consumer [68]. This switch is rapid, and potentiated by specialized isoforms of glycolytic enzymes that promote glucose uptake and phosphorylation only when glucose concentration is high. In addition, feeding alters hormones that mediate the phosphorylation and expression patterns of glycolytic and gluconeogenic enzymes to favor catabolism of glucose. Net hepatic uptake of glucose (1) reduces circulating glucose concentration, (2) replenishes hepatic glycogen, and (3) converts carbohydrate to lipid for long-term energy storage (Figure 13.8). In this section we consider the factors that regulate hepatic glucose uptake and utilization.

Glucose uptake

A family of facilitated glucose transporters with unique tissue distribution and kinetic properties emerged from the work of several laboratories in the late 1980s and early 1990s. The major glucose transporter isoform of liver and pancreatic islets, GLUT2, was the second member of the family identified. All facilitated glucose transporters are equilibrium-based transporters that are capable of bidirectional glucose transport across cellular membranes, with the directionality determined by the relative intracellular and extracellular glucose concentrations. GLUT2 has a low affinity ($Km > 10$ mM) but a high capacity for glucose transport relative to other members of its gene family. Thus GLUT2 transports large amounts of glucose into the hepatocyte, but only when the glucose concentration is high (10 mM). In normal physiology, liver takes up significant amounts of glucose only during meal absorption.

Glucokinase

Glucose phosphorylation in liver is primarily catalyzed by glucokinase (hexokinase IV). Like GLUT2, glucokinase (GK)
Figure 13.8 Glucose uptake by the liver is modulated by insulin and glucose concentration. Specialized isoforms of glucose transporter (GLUT2) and hexokinase (GK) equip the liver to use a net amount of glucose only when glucose concentrations rise above normal, for example after a meal. The accompanying elevation in insulin stimulates glycolysis and the conversion of glucose into glycogen and lipids. Glycolytic intermediates (i.e., glucose-6-phosphate, fructose-1,6-bisphosphate, xyulose-5-phosphate, etc.) allosterically activate glycogen synthesis and lipogenesis. Glucose disposal by glycogen synthesis is enhanced by its indirect synthesis via glycolytic intermediates in liver or gluconeogenic intermediates imported from peripheral tissue.

has a lower affinity for glucose and a higher catalytic capacity than the other members of its gene family (i.e., hexokinases I, II, and II) [69]. Glucokinase is expressed liver, the islets of Langerhans, and certain specialized neuroendocrine cells in the pituitary and gastrointestinal tract, whereas hexokinase I is found in brain, red blood cells and many other tissues, and hexokinase II is predominantly expressed in muscle and adipose tissue. Glucokinase has an S0.5 for glucose of about 8 mM, sigmoidal substrate dependency (indicated by a Hill coefficient of 1.7), and unlike hexokinases I and II, is not allosterically inhibited by the product of its reaction, glucose-6-P [69]. Thus, hepatocytes transport and phosphorylate glucose with kinetic features that allow net glucose uptake only during digestion.

In addition to the unique kinetics of hepatic glucokinase, its activity is also controlled by hormonal regulation of transcription and compartmental segregation. During fasting, glucokinase is sequestered in the nucleus by a glucokinase regulatory protein (GKRP). Ingestion of carbohydrate stimulates dissociation of glucokinase from GKRP and translocation of the enzyme from the nucleus to the cytosol where it can be active. Compartmentalization of glucokinase in the nucleus not only prevents glucose phosphorylation during gluconeogenesis, but also protects the enzyme from protein degradation. The acute induction of glucokinase by translocation to the cytosol is supplemented by a 20–30-fold increase in insulin-mediated glucokinase gene expression [70,71]. These large changes in glucokinase mRNA

are accompanied by more modest changes in glucokinase enzyme activity [71]. The time frame for changes in glucokinase enzyme activity due to insulin action is 30–60 min.

A key illustration of glucokinase in control of human fuel homeostasis comes from the discovery that a form of non-insulin-dependent diabetes mellitus (NIDDM) known as maturity-onset diabetes of the young (MODY) type 2 is caused by mutations in the glucokinase gene [72]. All MODY-2 patients are heterozygous, with one normal and one mutated glucokinase allele. Most, but not all, mutant enzymes associated with MODY-2 exhibit large decreases in enzymatic activity due to changes in kcat and S0.5 for glucose and Km for ATP. MODY-2 patients have impaired hepatic glucose disposal, leading to an increase in net hepatic glucose production and reduced glycogen storage compared to normal subjects [73]. In addition, patients with MODY-2 have a defect in glucose-stimulated insulin secretion, due to the important role that glucokinase plays in regulating the rate of glycolysis and thereby the production of key stimulus/secretion coupling factors in islet β cells.

Glucose phosphorylation as a therapeutic target for diabetes

Early experiments using genetic overexpression of glucokinase in liver of rodent models showed promise for the protection against hyperglycemia during diabetes, spawning the development of glucokinase activators [74]. These drugs interact with allosteric sites of glucokinase, thus promoting a conformation that exposes the catalytic domain and potentiates the activity of the enzyme [74]. Glucokinase activators have achieved beneficial effects on glycemia in human trials, in part by the putative activation of hepatic glycogen storage (a pathway that is impaired in the diabetic state). However, chronic genetic gain of function also causes fatty liver, hyperlipidemia, and increased insulin resistance [75]. These undesired effects appear to be linked to the overstimulation of the lipogenic pathway by increased glucose uptake. Unfortunately, some of these long-term side effects have been recapitulated in clinical trials, leading to tempered enthusiasm for glucokinase activation [76]. A related approach is to reduce hepatic glucose output by inhibition of glucose-6-phosphatase. Pharmacologic inhibitors of glucose-6-phosphatase have not been widely tested, but mice with a liver-specific loss of function have a dyslipidemia phenotype similar to glucokinase activation, in addition to glycogen storage disease [77]. The negative effect of these interventions on lipidemia raises concerns that sequestering carbohydrate in liver may improve glycemia at the expense of promoting dyslipidemia.

Glycogen synthesis

The normal postabsorptive human liver stores roughly 100 g or approximately 300 mM of glucose as glycogen which it releases during fasting to maintain blood glucose concentration. By 48 h of fasting, the human will have depleted most of its liver glycogen. Following a meal, when hepatic glucose-6-phosphate is plentiful, glycogen can be replenished within several hours. The synthesis of glycogen begins with conversion of glucose-6-phosphate to glucose-1-phosphate by phosphoglucomutase, followed by the "activation" of glucose-1-phosphate to UDP-glucose by UDP-glucose pyrophosphorylase. Finally, glycogen synthase uses UDP-glucose to add glucose molecules one at a time to a growing glycogen particle. The mature glycogen particle has a highly branched structure, which is created by a branching enzyme that moves blocks of glucose residues and links them in β-1,6-glycosidic linkages. Approximately half of hepatic glycogen synthesized after a mixed meal originates by the "direct" conversion of glucose to glycogen. The remainder is synthesized by an "indirect" pathway, which refers to the observation that some exogenous glucose is metabolized to trioses (i.e., at least DHAP and GA3P but perhaps all the way to pyruvate) before being converted to glycogen. The indirect pathway of glycogen synthesis is the consequence of continued gluconeogenesis during the fasted-to-fed transition [78], and may be reinforced by Cori cycling. The indirect pathway can account for approximately 30–60% of liver glycogen synthesis in humans, with the exact percentage dependent on the time elapsed between meals [79].

Glycogen synthase exists as two major isoforms and is regulated by both allosteric and covalent modification [12]. GYS1 is expressed in muscle and other cells which store glycogen, while hepatocytes express mainly GYS2. Glycogen synthase was one of the first enzymes to be identified whose activity is modified by phosphorylation, which occurs on multiple serine residues by several different kinases, notably PKA and GSK3α. Glycogen synthase activity is generally suppressed by phosphorylation, especially at site 2 (ser 7) [12]. PKA phosphorylation (glycogen synthase deactivation) is triggered by glucagon receptor activation, while GSK3 activity is suppressed (glycogen synthase activation) by insulin. The latter is mediated by Akt phosphorylation of GSK3, though GSK3 independent mechanisms are also involved [13] and are likely mediated by allosteric regulation. Glycogen synthase is potently activated by allosteric interaction with glucose-6-phosphate [80]. Thus, conditions such as elevated portal glucose and insulin lead to increased glucose transport and glucokinase activity, which favor increased glucose-6-phoshate concentration and induction of glycogen synthesis (Figure 13.8).

Phosphorylated glycogen synthase (deactivated) requires regulatory phosphatases for reactivation. Phosphatase activity is organized by scaffolding proteins known as glycogen targeting subunits [81]. These proteins are part of a large family of more than 50 protein phosphatase-1 (PP1) binding proteins that deliver the enzyme to a wide array of substrates and cellular addresses, allowing PP-1 to participate in diverse cellular processes such as glycogen metabolism, cell division, vesicle fusion, and ion channel function. G_L is a 35-kDa glycogen targeting protein that is preferentially expressed in liver. Protein targeting to glycogen (PTG), also known as PPP1R5, and a fourth form,

PPP1R6, are similar in size to G_L but are expressed in a wide variety of tissues. All of the targeting subunits are able to bind glycogen and PP-1, and exhibit varying capacities for binding of glycogen synthase, glycogen phosphorylase, and phosphorylase kinase [81]. Overexpression of PTG inhibits activation of glycogenolysis by the glycogenolytic cascade, and protects diabetic animals from hyperglycemia. However, constitutive activation of PTG also causes a form of glycogen storage disease in nondiabetic animals. PTG is particularly important for the regulation of indirect glycogen synthesis from gluconeogenic substrates [81]. Although the mechanism of PTG-mediated indirect synthesis of glycogen is not entirely clear, it appears to be related to accelerated disposal of glucose-6-P into glycogen, and a stimulation of gluconeogenesis. Thus PTG stimulates glycogen synthesis independent of glucose transport and GK activity.

Glycogen metabolism as a therapeutic target for diabetes

One approach to reducing hepatic glucose production during diabetes is to improve glycogen storage by activation of glycogen synthase and/or inhibition of glycogen phosphorylase. Glycogen synthase has been targeted by inhibition of GSK-3. GSK-3 inhibition increases glycogen storage and improves glycemia in a rodent model of type 2 diabetes [82]. However, glycogen synthase kinase also phosphorylates many other targets, making its mechanism difficult to decipher. Alternatively, glycogen phosphorylase can be inhibited directly by several classes of glucose analogues that either impair its allosteric activation or repress its ATP binding capability. These compounds improve glycemia in animal models of diabetes by increasing direct and indirect glycogen synthesis [83]. The adverse effects of pharmacologic promotion of glycogen storage are not completely known, but long term glycogen phosphorylase inhibition in animal models of type 2 diabetes can cause hepatomegaly, glycogenosis, and steatosis, side effects also common to glycogen storage diseases.

Glycolysis

Glucose-6-phosphate not used for direct glycogen synthesis can be metabolized in the glycolytic pathway. About half of the glucose taken up by liver during duodenal glucose absorption will undergo glycolysis to pyruvate. The resulting pyruvate can be used for lipogenesis and amino acid synthesis, lactate production, or cycled back to glucose-6-phosphate for indirect glycogen synthesis. There are 10 steps in the glycolytic pathway (Figure 13.3). Seven are catalyzed by enzymes with equilibrium constants that allow the reaction to proceed in either the "forward" (glycolytic) or "reverse" (gluconeogenic) direction dependent upon physiologic changes in the relative concentrations of substrates and products of the reactions. Three enzymatic steps, glucose phosphorylation by glucokinase (see earlier), the conversion of fructose-6-phosphate to fructose-1,6-bisphosphate by phosphofructokinase, and the conversion of phosphoenolpyruvate to pyruvate by pyruvate kinase are considered essentially irreversible due to a large release of free energy. Free energy is provided by the hydrolysis

of ATP in the case of the glucokinase and phosphofructokinase reactions, and via the favorable thermodynamics inherent in the conversion of an enolphosphate to a ketone in the pyruvate kinase reaction. In the previous section of this chapter, we discussed distinct enzymes that have evolved to circumvent the otherwise irreversible glycolytic steps and allow gluconeogenesis to occur. Thus, the forward reactions of glycolysis serve to produce pyruvate and also moderate gluconeogenesis during feeding. However, despite the elegance of the regulatory mechanisms of glycolysis, liver is, first and foremost, a gluconeogenic organ and gluconeogenesis remains modestly active even during the unfavorable conditions of a glucose load [42]. This residual activity provides a mechanism to prevent lactate build-up, and is the basis for indirect glycogen synthesis.

Regulation of phosphofructokinase (PFK)

Glucose-6-phosphate is rapidly isomerized to fructose-6-phosphate, and then undergoes phosphorylation to fructose-1,6-bisphosphate by PFK with ATP serving as the phosphate donor. PFK displays sigmoidal kinetics, typical of enzymes that are regulated by allosteric ligands. Its activity is regulated by hepatic energy charge, such that increases in the ratio of ATP:ADP inhibits enzyme activity. Citrate, the product of the first committed step of the TCA cycle, is also a potent inhibitor of PFK activity. This interaction reduces glycolysis and increases gluconeogenesis when TCA cycle intermediates are replete and energy production is high. However, the most important allosteric regulator of PFK activity in liver is fructose-2,6-bisphosphate (F-2,6-P2) [84 – 86]. F-2,6-P2 activates PFK at low micromolar concentrations via two main actions. First, it converts the kinetic profile of PFK from sigmoidal to hyperbolic with respect to the concentration of the PFK substrate fructose-6-phosphate. This change in activity increases the affinity (lowers the Km) of PFK for fructose-6-phosphate. Second, F-2,6-P2 relieves inhibition of PFK by ATP, such that higher concentrations of the nucleotide are required to suppress enzyme activity.

Biochemical and molecular studies revealed that the synthesis and degradation of F-2,6-P2 is catalyzed by a single protein with two distinct catalytic sites [87]. This protein was named 6-phosphofructose-2-kinase/fructose-2,6-bisphosphatase but is also known more simply as "the bifunctional enzyme." The bifunctional enzyme found in liver is regulated by fasting and glucagon action through cAMP-dependent PKA phosphorylation of a serine residue near its N-terminus [88]. Phosphorylation at this site inhibits the 2-kinase activity of the enzyme, and increases its bisphosphatase activity, resulting in a net decrease in F-2,6-P2 concentration within cells. This in turn leads to reduced affinity of PFK for its substrate fructose-6-phosphate and an increase in sensitivity of the enzyme to the inhibitory effects of ATP, leading to a net decrease in enzyme activity. Under these conditions, glycolysis is inhibited and gluconeogenesis is promoted.

In the transition from the fasted to the fed state, this regulation is reversed. Following a mixed meal, insulin and glucose levels rise in the blood while glucagon is decreased. These conditions cause dephosphorylation of the bifunctional enzyme, restoring its 2-kinase activity and causing a rapid increase in F-2,6-P2 levels. The dephosphorylation of the bifunctional enzyme appears to be mediated by a hexose-phosphate-sensitive protein phosphatase (PP2A). Xylulose-5-phosphate, an intermediate of the pentose phosphate pathway, was first discovered to activate PP2A [89]. Thus, carbohydrate-regulated PP2A provides a direct link between the postprandial change in intracellular glucose concentration and the reactivation of the 2-kinase activity of the bifunctional enzyme. In addition to the effect of glucose to activate PP2A, the increase in insulin levels in the postprandial state serves to stimulate degradation of cAMP to AMP via phosphodiesterases, thus decreasing the activity of PKA and contributing to maintenance of the bifunctional enzyme in a nonphosphorylated state.

Hepatic glycolysis as a therapeutic target for diabetes

Genetic modification of the bifunctional enzyme, so that it favors formation of F-2,6-P2 and activation of PFK, induces hepatic glycolysis, reduces glucose production and improves glycemia in diabetic models, without the deleterious effects on circulating FFA and TG levels that occurs with glucokinase activation [90]. Although both glucokinase and PFK activation stimulate hepatic glycolysis, unlike glucokinase activation, PFK activation appears to avoid induction of lipogenesis by preventing the accumulation of mono-phosphorylated glycolytic intermediates (i.e., xyulose-5P and glucose-6P) that activate ChREBP [90]. However, studies have been limited to genetic activation in rodent models and as was also the case for glucokinase, a more detailed understanding of the metabolic consequences of activation of the bifunctional enzyme/PFK is required, including better understanding of changes in lipid metabolism and the potential for hypoglycemia.

Regulation of pyruvate kinase (PK)

PK catalyzes the conversion of PEP to pyruvate, the last of the irreversible steps of glycolysis in liver. As described in the discussion of its role in gluconeogenesis (see earlier), pyruvate kinase is subject to both allosteric and transcriptional regulation (Figure 13.6). For example, liver isoform of pyruvate kinase (L-PK) is activated by the product of the PFK reaction, fructose-1,6-bisphosphate . This represents a "feed-forward" mechanism by which flux through an early step in glycolysis activates a later step. Similar to PFK, L-PK is sensitive to the energy charge of the cell, and its activity is decreased in the presence of a high ATP:ADP + AMP ratio. Similar to the bifunctional enzyme, L-PK is inhibited by PKA-mediated serine phosphorylation [91]. Phosphorylation increases the apparent Km of the enzyme for it substrate PEP, and renders the enzyme more sensitive to inhibition by a high energy charge (elevated ATP:ADP + AMP ratio).

Like the other key glycolytic enzymes, transcription of the L-PK gene is decreased by fasting or insulinopenic diabetes, and is increased in the fed state or by insulin injection. Glucose appears to be a more direct and potent regulator of L-PK transcription than insulin, which may be acting to antagonize the effects of glucagon by activating phosphodiesterases and lowering cellular cAMP levels. In addition, the same protein phosphatase that dephosphorylates the bifunctional enzyme when sugar phosphate levels are elevated also dephosphorylates and activates ChREBP. ChREBP stimulates transcription of L-PK, as well as lipogenic genes such as acetyl-CoA carboxylase and fatty acid synthase. Thus, a rise in circulating glucose concentration and a proportional increase in the rate of hepatic glycolysis and pentose monophosphate shunt activity in the fasted-to-fed transition is translated into an increase in 2-kinase activity of the bifunctional enzyme via activation of PP2A, resulting in an increase in F-2,6-P2 levels and increased flux through PFK to generate fructose-1,6-bisphosphate. This intermediate then serves as a feed-forward activator of a later step in glycolysis, L-PK. Finally, allosteric activation of pyruvate kinase is supplemented by another action of the Xu5P-regulated protein phosphatase, the dephosphorylation and activation of the ChREBP transcription factor which stimulates L-PK gene transcription.

Pyruvate dehydrogenase and lipogenesis

The generation of pyruvate via glycolysis and L-PK brings the chapter full circle. Tracer experiments in humans estimate PDH flux to be very small in the postabsorptive liver [36,37]. However, in the fed state activation of hepatic lipogenesis requires activation of PDH flux to generate acetyl-CoA from carbohydrate. PDH consists of three subunits (E1–E3) that catalyze the sequential decarboxylation, acetyl-CoA formation and reduction of NAD+ to NADH, respectively. These subunits exist in a super-complex of more than 200 of these subunits called the PDH complex (PDC) [92]. During fasting, PDH activity is kept suppressed by pyruvate dehydrogenase kinase (PDK) which phosphorylates one or more of three serine residues on the E1 subunits [33]. PDK is associated to the E2 subunit of the PDC and its activity is acutely regulated by its own substrates and products (ATP/ADP) as well as the substrates and products of PDH (NADH/NAD+ and acetyl-CoA/CoA). Upon carbohydrate ingestion, PDH is reactivated by dephosphorylation of these sites through the actions of pyruvate dehydrogenase phosphatases (PDP), which are also components of the E2 subunits of the PDC and broadly regulated by Ca2+ and Mg2+. The main regulation of PDH phosphorylation appears to be through modification of PDK activity [33]. Upon carbohydrate ingestion, fatty acid oxidation is suppressed, PDK is deactivated, and PDPs dephosphorylate to relieve the suppression of PDH.

In coordination with the conversion of pyruvate to acetyl-CoA, high glucose activates ChREBP and induces the expression ACC and FAS, which facilitates the conversion of acetyl-CoA to lipids. During this process, ACC catalyzed

carboxylation of acetyl-CoA to malonyl-CoA suppresses fat oxidation through allosteric inhibition of CPT-1 [43]. In normal physiology, elevated glucose is always accompanied by high insulin, which suppresses the genes of fat oxidation and induces SREBP. SREBP, in turn, promotes the expression of lipogenic genes and enhances the conversion of acetyl-CoA to lipids [93].

Summary

The liver has been studied for its metabolic characteristics for more than 200 years. The liver's ability to produce or utilize glucose is the foundation of glycemic control. During fasting, liver releases glucose from glycogen stores and uses gluco-neogenesis to produce glucose from pyruvate, lactate, amino acids, and glycerol. During prolonged fasting, gluconeogenesis is upregulated to compensate depleted glycogen levels and prevent major changes in blood glucose concentration. Upon feeding, liver rapidly converts to an organ that utilizes more glucose than it produces. Postprandial glucose uptake by liver replenishes glycogen and provides substrate for lipid synthesis for long-term energy storage. A large proportion of glycogen is formed by "indirect" synthesis, a process driven by the simultaneous activity of glycolysis and gluconeogenesis. Lipids are synthesized from acetyl-CoA derived from the activation of glycolysis and PDH. These elegant shifts in metabolism are regulated by transcription, posttranslational modification, allosteric and the substrate regulation of several key enzymes in the gluconeogenic and glycolytic pathway. Glucagon and other counterregulatory hormones activate transcription factors and co-activators that induce the expression and stability of gluconeogenic enzymes, while insulin opposes these effects and stimulates glucose uptake. Defects in any of these mechanisms can lead to loss of glycemic regulation.

Introduction

Glucose

Glucose is widespread in living organisms and, with protein and fat, completes the triad of the major metabolic fuels. To a much lesser extent than in plants, glucose also constitutes a building block for structural and enzymatic components of cells as well as the extracellular matrix. As a metabolic substrate, glucose is present in organisms essentially in its simple, monomeric form (α-D-glucopyranose) and as a branched polymer of α-glucose, namely glycogen. Disaccharides of glucose (lactose, maltose, and sucrose) are quantitatively less important. Glucose is present in plasma water at a concentration that — in a healthy adult who has fasted overnight — ranges between 3.6 and $5.5\,\text{mmol}\,\text{L}^{-1}$ ($65\text{–}99\,\text{mg}\,\text{dL}^{-1}$). A family of proteins residing in the plasma membrane (and in microsomal membranes) can specifically and reversibly bind glucose molecules, and transfer them across cell membranes in both directions. Of such proteins, known as glucose transporters (or, more generally, SoLute Carriers 2A or SLC2A), there are 14 different species that have so far been identified [1,2]. They differ from one another in both tissue distribution and physiologic regulation, particularly with respect to sensitivity to insulin stimulation. It is usual for more than one species of glucose transporter to be expressed in a tissue. One type of glucose transporter (GLUT4) represents the major insulin-stimulated glucose transporter *in vivo*, and this transporter is abundantly expressed in the classic insulin-sensitive tissues (adipocytes, brown fat, and skeletal, cardiac, and smooth muscle). Variable dominance of the other types of glucose transporters is found in tissues in which glucose metabolism does not respond to insulin acutely (erythrocyte, liver, kidney, brain, pancreatic β cells).

A non-insulin-regulatable transporter (GLUT1) effects facilitated glucose diffusion in red blood cells (RBCs). The abundance of this transporter in RBCs has the following physiologic consequences:

1. Glucose diffuses very rapidly across RBC membranes, with an estimated equilibration time of only 4 s (a total RBC mass of 25×10^9 cells with a mean diameter of 7 μm and a spherical shape occupies a surface area of approximately $4\,\text{m}^2$) [3]. The rate of glycolytic utilization of transported glucose by the erythrocyte mass is estimated to be $25\,\mu\text{mol}\,\text{min}^{-1}$ or about $6\,\mu\text{mol} \times \text{min}^{-1} \times \text{m}^{-2}$ of diffusion surface. Since this rate is ~17,000 times less than the rate of glucose transport in these cells, glucose concentration will be the same in plasma and erythrocyte water. Plasma proteins make up ~8% of plasma volume, while RBC proteins and ghost occupy about 38% of packed red cell volume (which, in turn, averages 40% of blood volume). Thus, 20% (i.e., $0.38 \times 0.4 + 0.08 \times 0.6 = 0.2$) of total blood volume is inaccessible to glucose. It follows that glucose concentration should be identical in plasma and RBC water under most circumstances, and that a *blood water* glucose concentration of $5.0\,\text{mmol}\,\text{L}^{-1}$ translates into a *plasma* glucose concentration of $4.6\,\text{mmol}\,\text{L}^{-1}$ and a whole-blood glucose concentration of $4.0\,\text{mmol}\,\text{L}^{-1}$, that is, a 15% systematic difference between plasma and *whole-blood* glucose level under typical conditions of hematocrit, proteinemia, and erythrocyte volume.

2. As both RBC and plasma convey glucose, the total amount of the sugar reaching any given organ is the product of arterial whole-blood glucose concentration times the total blood flow to that organ. Similarly, the total amount of glucose leaving a body region is the product of whole-blood glucose level in the venous effluent times the blood flow rate. Thus, under steady-state conditions of blood flow (F), arterial glycemia (A) and organ metabolism, the net balance of glucose movement across a body region is given by the product of blood flow and the arteriovenous ($A\text{-}V$) whole-blood glucose concentration

Net balance = Input - Output; U-R = F×(A–V)
Figure 14.1 Schematic representation of substrate (i.e., glucose) exchange across an organ (i.e., the liver) that both irreversibly removes the substrate (i.e., glucose) and adds it to the systemic circulation. A, arterial concentration; F, blood flow; V, venous concentration.

difference [$(A\text{-}V) \times F$, or Fick principle] (Figure 14.1) [4]. It is evident that the use of *plasma* flow rate and plasma glucose concentration systematically underestimates the net organ balance of glucose (and, for that matter, of any substance that travels in plasma as well as in erythrocytes, for example lactate and some amino acids). In fact, plasma flow is less than blood flow by an amount equal to the hematocrit ($\sim$40%), while plasma glucose is higher than whole-blood glucose by only 15% ($0.6 \times 1.15 = 0.69$, i.e., a 31% underestimation).

At least two non-insulin-regulatable glucose transporters (GLUT1 and GLUT3) have been identified in the blood–brain barrier and placenta [1,2], where transendothelial glucose passage occurs via facilitated diffusion. This is the structural basis for the long-held notion that brain and placental glucose utilization are not regulated by insulin, so that vital functions for the adult and fetal organism can be maintained in the face of variable metabolic conditions.

In general, diffusion of glucose from the intravascular compartment into the interstitial fluid space is very rapid. Whether this is accomplished by facilitated diffusion mediated by specific cell transporters (as in the brain) or by simple diffusion through intercellular clefts of endothelial cells is still uncertain. A lower limit of glucose diffusion through endothelial membranes is represented by cellular glucose uptake (which does not include glucose back-diffusion into the intravascular compartment), and can be estimated by carrying out the following calculation. In healthy subjects under conditions of maximal stimulation (i.e., combined hyperinsulinemia and hyperglycemia), whole-body glucose uptake can reach $12\,mmol\,min^{-1}$ which, for a total capillary surface of $700\,m^2$ available for diffusion (and considering a mean surface of $19{,}000\,\mu^2$ per capillary [5]), corresponds to $0.3\,pmol\,min^{-1}$ per capillary. Thus, about 200 billion glucose molecules must pass through each capillary surface each minute to travel through the interstitial space.

Direct measurement of interstitial glucose concentrations has proven to be difficult, and has yielded conflicting results. Difficult as it may be to measure or calculate this "bathing" concentration of glucose, it is this concentration that dictates the activity of cellular glucose transport together with the state

of specific activation of the glucose transporter. In addition to substrate mass action, cellular glucose uptake is influenced by changes in blood flow and hormonal stimulation by insulin. Thus, glucose metabolism is regulated by a distributed control between tissue glucose delivery (blood flow), transit through the interstitium, plasma membrane glucose transport and glucose phosphorylation (hexokinase) [6,7].

Blood flow varies considerably between insulin-sensitive tissues. Thus, basal blood flow to muscle and adipocytes in low (0.03–$0.04\,mL\,min^{-1} \times$ gram tissue) [8] and blood flow can play an important role in glucose delivery, cellular uptake, and subsequent metabolism. Baron [9] was amongst the first to show that physiologic hyperinsulinemia, while maintaining euglycemia, stimulated muscle blood flow resulting in enhanced muscle glucose uptake. The insulin-mediated increase in muscle blood flow results from two separate effects: (i) relaxation of resistance of vessels, and (ii) recruitment of previously unperfused muscle tissue secondary to relaxation of terminal arterioles [8]. This recruitment effect of insulin has been elegantly documented using microbubbles in combination with contrast-enhanced ultrasonography in rodents and humans [8]. The result is expansion of the capillary surface area for nutrient and insulin delivery. Impaired insulin-mediated vasodilation is associated with metabolic resistance to the stimulatory effect of insulin on muscle glucose utilization in type 2 diabetic and obese nondiabetic individuals [8,9]. Evidence in humans has demonstrated that the insulin concentration in lymph and interstitial fluid is considerably less than in plasma [10,11]. Transport rates of large molecules, such as insulin, into the interstitial space, and thus the cell membrane, is slow. Insulin binding to its receptor in the vascular endothelium and subsequent incorporation into caveolae are involved in the transcytosis of the hormone from the intravascular to the interstitial space [8]. Since the rate of insulin entry into skeletal muscle appears to be a critical step for insulin action, elucidation of the molecular and anatomical mechanisms involved in the transvascular process is likely to produce novel insights into the etiology of metabolic insulin resistance.

Another non-insulin-regulatable glucose transporter (GLUT2) is abundantly expressed in the plasma membrane of liver, kidney, intestinal cells, and pancreatic β cells [1,2]. In liver and kidney, net glucose release occurs *in vivo*. Thus, in the only organs in the body in which the presence of glucose-6-phosphatase (G6Pase) — the enzyme catalyzing the formation of free intracellular glucose from glucose-6-phosphate (G6P) — makes glucose available to the circulation, the transporter is of a type that only responds to the concentration gradient between the internal and external side of the plasma membrane. This ensures that, when insulin is around to stimulate inward glucose transport in tissues with sensitive transporters, the liver can release glucose into the blood stream as long as sufficient G6P is derived from glycogenolysis or gluconeogenesis (or both) and sufficient G6Pase activity is there to accumulate free glucose on the inside of the plasma membrane. Under these conditions of reversed gradient, the presence of insulin-responsive glucose transport

activity on hepatocyte cell membranes would enhance glucose *outflow*, thereby opposing the plasma glucose-lowering action of insulin. In contrast, physiologic control of the direction and rate of glucose flux through the hepatocyte membrane is not on the transport step but on intracellular processes.

GLUT4 is the insulin-regulated transporter present in muscle and adipocytes [1,2]. In the fasting state, less than 5–10% of GLUT4 is present in the plasma membrane. The other 90% resides in GLUT4 storage vesicles (GSV) and endosomes within the cell. Following stimulation by insulin, the GSV translocate to the plasma membrane via exocytosis and mediate glucose transport into myocytes and adipocytes. Following binding of insulin to its receptor and activation of the insulin signaling pathway, a series of small (20–35 kDa) GTPases are activated and they interact with multiple motor proteins, membrane tethers, and fusion-regulating proteins to direct flow of the GSV to the plasma membrane [1,2]. GSV exocytosis can be divided into three separate processes: translocation to the cell periphery, targeting of the vesicles to the plasma membrane, and ultimately fusion with the cell membrane. In myocytes the phosphoinositol-3-kinase (PI3K) signaling pathway is an absolute requirement for GLUT4 exocytosis. In individuals with type 2 diabetes mellitus (T2DM) defects in both the PI3K signaling pathway and in the GLUT4 exocytotic pathway contribute to insulin resistance in muscle and adipocytes [12]. Following exposure to insulin, GLUT4-containing vesicles can be demonstrated in the cell periphery and plasma membrane within 5 minutes. Disruption of the microtubular/actin system within myocytes/adipocytes completely inhibits insulin-stimulated GLUT4 translocation. Fusion of GSV with the plasma membrane requires interaction with SNARE (soluble N-ethylmolemide-sensitive factor attachment receptor regulatory) proteins including VAMP2, STX4, SNAP23, and others. In adipocytes a PI3K-independent signaling pathway mediated via the adaptor protein APS (adaptor protein with pleckstrin homology and Src homology domains) also plays an important role in GLUT4 exocytosis; in myocytes a role for the insulin-stimulated APS pathways has yet to be defined [2].

In summary, the differential distribution and acute insulin sensitivity of the various classes of glucose transporters provide the backbone for the functional characteristics of glucose diffusion and exchange in the body. On the whole, free glucose is present in blood water, interstitial fluid, and the intracellular water compartment of insulin-independent tissues (liver, brain, kidney, intestine, placenta) in total amounts which, in the overnight-fasted healthy adult, average 80 mmol (14 g or 1.2 mmol kg^{-1} of body weight), of which one fifth is in the blood volume. Free glucose is found at concentrations that (a) are uniform in the intravascular water compartment; (b) decline across the interstitial space toward the cell; (c) fall precipitously within cells that consume glucose avidly (e.g. brain) or in which glucose transport is relatively slow in the basal state (e.g. muscle, adipose tissue); (d) are increased in the cytoplasm of cells that produce free glucose (mostly liver);

and (e) gradually and continuously decrease in the vascular bed as arterial blood turns into capillary blood and then runs back toward the right heart as venous blood. The regional characteristics of tissue composition, blood flow rate, capillary density (i.e., the average distance between the capillary axis and the cell surface), and cellular glucose uptake concur to determine the *A-V* glucose gradient in any region of the body. Glycogen is present in most cells in cytoplasmic granules that encase the enzymes that regulate its metabolism. In normal humans, the largest part of glycogen stores is in liver and skeletal muscle. In the former, 3–4 g of glycogen are packed in each 100 g of parenchyma; in striated muscle, the concentration is much lower (0.7–1.0% weight by weight). As a consequence, a normal human liver (1.5 kg) contains some 60 g of glycogen, whereas muscle (28 kg) depots keep 250 g. Thus, approximately 25 times more glycosyl units are stored in intracellular depots as glycogen than are dissolved in body water as free glucose. Glycogen metabolism is controlled by irreversible cascades of enzymatic reactions ultimately acting upon the proximal enzymes that catalyze glycogen synthesis (glycogen synthase) and degradation (glycogen phosphorylase) (see subsequent discussion).

Key points

- Glucose concentration is on average 15% higher in the plasma than the whole-blood glucose under ordinary circumstances.

- Arterial glucose levels are higher than capillary glucose concentrations, which in turn are higher than venous levels. The extent of these differences depends on the circulatory region and on its rate of glucose utilization.

- Both plasma and erythrocytes carry glucose to and from consuming tissues.

- In brain, liver, kidney, intestine, and placenta, glucose uptake is insulin independent; in adipose tissue, skeletal and heart muscle, glucose uptake depends on insulin.

- Tissue-specific glucose transporters (GLUTs) mediate glucose uptake in insulin-sensitive and insulin-insensitive tissues.

- The whole-body reserves of carbohydrate are quite small.

- Insulin-mediated vasodilation, involving recruitment of unperfused capillary beds, plays a role in regulating muscle glucose uptake.

Glucose metabolism

Introduction

Any given concentration of glucose in plasma (and in the space in equilibrium with plasma) is the result of simultaneous release of glucose into the circulation and uptake of glucose from the blood stream into cells. Whenever plasma glucose concentration is stable, the concurrent rates of its release and overall uptake must be equal. Glucose turnover (TR) is this rate of constant flux through its system. Accepted terminology

refers to stationary conditions of glucose concentrations and flux rate as the "steady state," with the understanding that any physiologic steady state is only an approximation of the true, ideal steady state. Furthermore, the "glucose system" refers to the whole space or volume into which glucose is present as free glucose, regardless of how many compartments this system consists of, where they are physically located in the body, and how they are interconnected. Finally, the reference pool for glucose kinetics customarily is the plasma (or whole blood), for in most clinical or experimental circumstances the plasma is the only site accessible for sampling. When the plasma glucose concentration changes over time, one rate of glucose flux (entry or removal) is being exceeded by the other. Under these non-steady-state conditions, the glucose rates of entry and removal are conventionally termed rate of appearance (Ra) and disappearance (Rd), respectively. The glucose system is strongly homeostatic with respect to glucose levels, in that the normal variations in human plasma glucose concentration throughout a day of life are confined within a surprisingly narrow range. It should be recalled that glucosuria is called upon whenever glycemia exceeds the renal threshold, $\sim$180 mg dL^{-1}, as if a safety measure had been set to cope with emergency when metabolic control fails. These considerations alone indicate that the body does not tolerate either hypoglycemia or hyperglycemia. For the former, the obligate dependence of brain function on the use of glucose as fuel classically has been offered as a rational explanation. For hyperglycemia, the evidence—and hence the concept—that high glucose levels, if not immediately life-threatening, are nonetheless intolerable to bodily functions, is more recent but no less compelling, and currently goes under the name of "glucose toxicity" (see Chapter 27).

Methods

Under conditions of an overnight fast, the liver accounts for $\sim$80% of glucose production with the remaining $\sim$20% coming from the kidney [12,13]. Placing catheters across the splanchnic bed (one in a hepatic vein and another in any artery) and measuring splanchnic blood flow (e.g. by infusing a dye, such as indocyanine green, that is only cleared by the hepatocyte) allows the measurement of glucose turnover as the product of A-V difference and blood flow (Figure 14.1). However, the liver and extrahepatic splanchnic tissues (gut, pancreas, spleen, etc.) also take up glucose; the application of the Fick principle allows one to estimate the net balance between glucose uptake and release in the splanchnic area, not the total rate of glucose turnover (Figure 14.1). One must resort to glucose tracers, such as radioactive (e.g. ^{3}H-glucose or ^{14}C-glucose) or stable (e.g. ^{2}H-glucose or ^{13}C-glucose) isotopes of glucose. The kidney, like the liver, also simultaneously takes up and releases glucose. By combining tracers and renal vein catheterization with measurement of renal plasma flow (using para-aminohippurate), one can quantitate the bidirectional flux of glucose across the kidney, similar to that described across the splanchnic bed. Details of the tracer technique as applied to glucose turnover measurement can be found in several reviews and treatises [14,15].

A tracer can be administrated as a pulse injection or constant intravenous infusion or combination thereof. Under steady-state conditions applying to both tracee (i.e., glucose) and tracer, glucose turnover rate is simply given by the ratio of the tracer infusion rate (IR) to the equilibrium plasma glucose specific activity (SA = tracer/tracee concentration). Equilibrium is the time (usually 2–3 h after starting the tracer infusion) when unchanging plasma tracer concentrations indicate that glucose specific activity has become uniform throughout its distribution space. This formula, IR/SA, is not based on any assumptions other than the attainment of equilibrium. When non-steady-state conditions prevail, this approach cannot be used because either the tracer or the tracee concentration (or both) change over the period of measurement. Unfortunately, in the patient with diabetes the glucose system is unsteady for most of the time, precisely because homeostasis has been lost. However, practicable ways around the problem do exist [16] and the reader is referred to several reviews of the topic [14,15].

As discussed earlier, glucose tracers are useful in the study of regional metabolism in two respects:

1 For organs in which glucose uptake and release occur simultaneously (typically, the liver and kidney) the A-V difference for the tracer offers a measure of absolute uptake (for the tracer is not produced by the organ), while absolute release can be calculated as the difference between net balance (as measured by the Fick principle) and uptake. If A^* and V^* and A and V are the arterial and venous tracer and tracee concentrations, respectively, and F is the blood flow, the absolute glucose uptake rate is $(GU) = (A^*\text{-}V^*)/A^* \times A \times F$ *and* the net balance is $(NB) = (A\text{-}V) \times F$. The rate of glucose production is $(GP) = NB - GU = F \times A \times (V^*/A^*\text{-}V/A)$.

2 As tracer glucose is metabolized, its label will appear in one or more degradation products (P^*). For any degradation product, the ratio of its labeled moiety to the specific activity of glucose (i.e., $P^* \times [A^*/A]^{-1}$) is the amount of that product generated from glucose (in units of concentration). For example, measuring ^{14}C-lactate and ^{14}C-carbon dioxide during the infusion of ^{14}C-glucose makes it possible to estimate the amounts of glucose that were glycolyzed and completely oxidized, respectively. If, then, the kinetics of precursor and product are separately determined, all of these precursor–product relationships can be converted into fluxes of interconversion, regionally as well as at the whole-body level.

An important concept in kinetics and physiology is that of glucose clearance. When referred to the plasma volume, glucose clearance is the volume of plasma that is completely cleared of glucose per unit time. Glucose clearance (CR) is related to glucose turnover rate as follows: TR = CR $\times$ G (where G is the glucose concentration in the same pool, plasma or blood, arterial or venous, in which the tracer concentration was determined). At the level of an organ that only consumes glucose—that

is, in which $U = F \times (A\text{-}V)$ (Figure 14.1) — glucose clearance is also given by U/A or $[F \times (A\text{-}V)/A]$. The latter formula calculates *net* glucose clearance in organs in which there is simultaneous glucose uptake and release. As the ratio $(A\text{-}V)/A$ is the extraction ratio (or fractional extraction) of glucose, the product $[F \times (A\text{-}V)/A]$ is the fraction of the flow to an organ that is totally cleared of glucose at any glucose concentration. Thus, the clearance rate is a measure of the efficiency of glucose removal regardless of glycemia. As such, it "feels" the impact of specific stimuli (e.g. insulin) independently of the mass action of glucose. It is important in this context to bear in mind that the tracer method actually measures glucose clearance (as the ratio of the tracer infusion rate to the equilibrium plasma tracer concentration), and derives glucose turnover rate as the product of clearance and glycemia.

The basal state

Glucose production

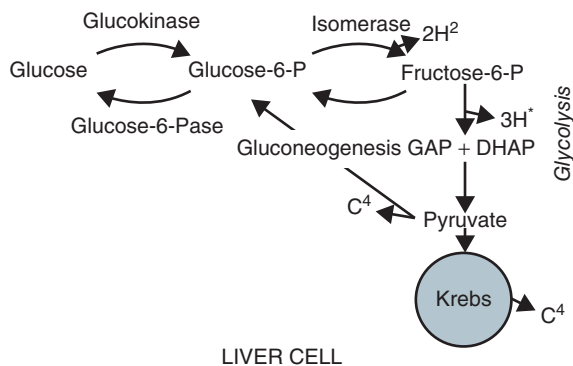
By convention, the basal state is the metabolic condition prevailing in the morning after an overnight (10–14 h) fast. This time marks the end of the longest period of fasting in ordinary life and also is the most common point of clinical observation and physiologic measurements. The true value of basal endogenous (liver plus kidney) glucose production is the one that would be reproducibly measured with the use of an irreversible glucose tracer, which loses its label at the earliest possible intracellular step without ever getting it reincorporated into a circulating tracer molecule [14,15]. Carbon isotopes systematically underestimate glucose turnover because of the efficient reincorporation of carbons (via three-carbon fragments such as lactate) into new glucose in the liver (via gluconeogenesis) (Figure 14.2).


Figure 14.2 In liver cells, hydrogen labels in position 3 of the glucose molecule are almost exclusively lost at triosephosphate step: they can therefore travel backwards through the phosphoglucoisomerase reaction to glucose-6-phosphate, and on to free glucose via glucose-6-phophatase. In contrast, hydrogen labels in position 2 are largely lost in the isomerize reaction (by 75% for each complete cycle), and are therefore prevented from recycling to the free glucose pool. Carbon labels of glucose are lost to carbon dioxide following complete oxidation of glucose in the Krebs cycle, but can also recycle to glucose *de novo* through three-carbon precursors via gluconeogenesis.

Gluconeogenesis can occur in other tissues (e.g. skeletal muscle [17]), but the absence of significant G6Pase activity in tissues other than the liver and kidney prevents labeled breakdown products from re-entering the circulation as glucose, where they would alter the estimation of glucose turnover. As for tritiated or deuterated isotopes, labels in positions 3, 4, 5, and 6 are lost at the triosephosphate step or further downstream in anaerobic glycolysis, while a label in position 2 is largely lost at the phosphoglucoisomerase step (a near-equilibrium reaction) soon after phosphorylation [14,15,18] (Figure 14.2). In neither case does the detached label (essentially in equilibrium with the hydrogen of the body water pool) recycle back into a new glucose molecule to any detectable extent.

In the basal state, glucose output in healthy adults averages $\sim$840 μmol min^{-1} (or $\sim$12 μmol min^{-1} per kg of body weight) [19]. The dispersion around this mean estimate is significant (20–30%), with an unknown contribution of genetic and environmental factors. In nondiabetic subjects total body endogenous glucose output variability is wide and is largely explained by the amount of lean mass [20] and this, in turn, explains differences in total endogenous glucose output due to sex, obesity, and age. Under standard nutritional conditions, the fasting liver depletes its glycogen stores at a rate of about 5% per hour, such that glycogen depots are empty after 24 h. Since fasting can be prolonged well beyond 24 h, obviously gluconeogenesis must progressively replace glycogenolysis as fast continues [21,22].

In animal species in which the basal rate of glucose turnover is higher than in humans (e.g. dogs, 20 μmol min^{-1} kg^{-1}; rats, 40 μmol min^{-1} kg^{-1}), the limited capacity of the liver to store glycogen confers an increasing role to gluconeogenesis for the maintenance of basal glycemia. This limitation on glycogen accumulation has an anatomical basis: overcrowding of cytoplasm with glycogen granules impairs cellular functions, leading to infiltration of nuclei and, eventually, to cell death, as observed in several glycogen storage diseases. In normal healthy adults in the overnight fasted state, gluconeogenesis and glycogenolysis approximately equally contribute to hepatic glucose release [21–23]. In obese nondiabetic and in type 2 diabetic subjects the contribution of gluconeogenesis to hepatic glucose production is increased compared to lean normal glucose tolerant subjects [22,24,25]. In subjects with variable degrees of overweight and hyperglycemia, it has been established that the percent contribution of gluconeogenesis to fasting glucose release rises with increasing body mass index (by $\sim$1% per body mass index unit) and increasing fasting hyperglycemia (by $\sim$3% per mmol L^{-1}) [22]. In healthy subjects, physiologic hyperinsulinemia suppresses percent gluconeogenesis by $\sim$20% while completely blocking glycogenolysis [24,26]. As long as hyperinsulinemia restrains glycogenolysis — as is the case of obese nondiabetic subjects — basal endogenous glucose release will be normal in absolute terms. As glycogenolysis also becomes resistant to the inhibitory effect of insulin — as in the case of type 2 diabetic patients [26] — fasting glucose output

will increase [12,27]. Circulating lactate, pyruvate, glycerol, alanine, and other gluconeogenic amino acids are important gluconeogenic precursors [28,29]. However, transsplanchnic catheterization in humans has shown that net uptake of circulating precursors accounts for less than 50% of endogenous glucose production in the basal state [28,29]. The discrepancy (amounting to $1-2\,\mu mol\,min^{-1}\,kg^{-1}$) between radioisotopic estimates of basal gluconeogenic rate [22] and accountable circulating precursors [28,29] indicates that the blood is not the only route of gluconeogenic supply. Within the splanchnic area, the intestine returns $10-20\%$ of its glucose uptake to the liver as alanine ($0.5\,\mu mol\,min^{-1}\,kg^{-1}$) [30], thereby filling part of the gap. Intrahepatic lipolysis (i.e., glycerol), proteolysis, and glycolysis theoretically could guarantee ample provision of precursors as an alternative or in addition to those in the circulation. However, the liver can supply gluconeogenic amino acids only at the cost of breaking down liver tissue. It has been calculated that to produce glucose at a rate of $5.6\,\mu mol\,min^{-1}\,kg^{-1}$ (i.e., ~50% of fasting hepatic output) would require the consumption of all the protein in 40 g of liver tissue every hour [22]. Thus, both the amount and source of the gluconeogenic flux in fasting humans remain elusive.

The main control of basal hepatic and renal glucose production is exerted by the sum of several neurohormonal and metabolic influences, some stimulatory, others inhibitory. Figure 14.3 depicts the control system in the liver as a simple balance between inhibition and stimulation. Both parasympathetic and sympathetic fibers reach the liver via the splanchnic nerves, thereby supplying autonomic nervous modulation of both glucose production and uptake. An increase in parasympathetic impulses restrains glycogenesis and enhances glycogen synthesis, while an increase in sympathetic outflow to the liver stimulates glucose output via potentiation of both glycogenolysis and gluconeogenesis [31]. In humans, the influence of the sympathetic nervous system on hepatic glucose metabolism can be demonstrated under conditions of acute stimulation, but the contribution of the autonomic nervous system to the maintenance of basal glucose production remains undetermined.
Figure 14.4 Splanchnic glucose uptake (cross-hatched bars) and hepatic glucose production (solid bars) in healthy subjects under four experimental conditions: (i) overnight fast; (ii) hyperglycemia ($+125\,mg\,dL^{-1}$) with somatostatin blockade of endogenous insulin release (Low insulin); hyperglycemia ($+125\,mg\,dL^{-1}$) with somatostatin plus insulin replacement to maintain the fasting insulin concentration constant (Basal insulin); hyperglycemia ($+125\,mg\,dL^{-1}$) with endogenous insulin ($55\,uU\,mL^{-1}$) release. Note that hyperglycemia per se inhibits hepatic glucose production and that hyperglycemia acts synergistically with insulin to inhibit liver glucose output. In contrast, hyperglycemia stimulates glucose uptake to approximately the same extent in the presence of low, basal, or high insulin, that is, mostly by mass action. Source: Drawn from the data presented in DeFronzo et al. 1983 [32].

As for metabolic signals, hyperglycemia per se can effectively inhibit liver glucose output in normal humans [29]. As shown in Figure 14.4, during constant hyperglycemia (maintained by the hyperglycemic clamp technique) hepatic glucose production is significantly reduced in comparison with euglycemia even when the endogenous insulin response to hyperglycemia is blocked by somatostatin. It is evident from Figure 14.4 that normally the two inhibitory signals, hyperglycemia and endogenous hyperinsulinemia, concur to shut off glucose production [32–34]. Hypoglycemia by itself may trigger an increase in hepatic glucose release even when one or more counterregulatory influences are paralyzed [35]. Studies in humans [33,36] and in dog [37] have established a role for a portosystemic glucose concentration gradient in controlling hepatic glucose handling. Thus, intraportal glucose infusion specifically alters the partitioning of a glucose load among tissues, by stimulating net hepatic glucose uptake and reducing peripheral glucose uptake. Of other metabolic signals, it is difficult to demonstrate in humans an increase in hepatic glucose production by infusing large quantities of glycerol, lactate, or a mixture of amino acids, as long as there is physiologic hyperinsulinemia to balance out such a gluconeogenic push.

Note, that an increased provision of precursors may well lead to increased intrahepatic formation of glucose-6-phosphate (G6P), but the eventual fate of this intermediate may be glycogen rather than free glucose if control of the rate-limiting step for free glucose production, namely G6Pase activity, is not simultaneously loosened. Free fatty acids (FFA) stand out as one substrate that may play an important role in setting the level of hepatic glucose production. Since only odd-chain FFA

Figure 14.3 Inhibitory (on the left) and stimulatory (on the right) factors controlling hepatic glucose production.

(i.e., propionate) can donate their carbon to oxaloacetate in the tricarboxylic acid cycle, FFA do not represent an important precursor for gluconeogenesis. Most physiologic FFA are even-chain, and they exchange their carbon moieties with tricarboxylic acid cycle intermediates but do not contribute to *de novo* glucose synthesis. Nevertheless, enriching the perfusion medium of isolated rat liver with oleate or palmitate induces an increase in new glucose formation from lactate or pyruvate [38]. Moreover, FFA and/or products of their oxidation (e.g. citrate and acetyl-CoA) activate key gluconeogenic enzymes such as pyruvate carboxylase, phosphoenol-pyruvate carboxykinase, and G6Pase [38,39]. In addition, raised FFA concentrations *in vivo* are accompanied by raised glycerol levels, resulting from hydrolysis of triglycerides. Therefore, accelerated lipolysis normally supplies both the stimulus (FFA) and the substrate (glycerol) for gluconeogenesis. Finally, the liver takes up FFA avidly (with an extraction ratio of ~30%), and oxidizes them efficiently (as indicated by the low respiratory quotient of the organ) [40,41]. Thus, there are all the requisites to consider FFA oxidation in the liver as the energy-providing process that is coupled to energy-requiring gluconeogenesis. In isolated hepatocytes, FFA in micromolar amounts inhibit glycogen synthase [42], which suggests that an additional interaction of this substrate with hepatic glucose metabolism may be at the level of glycogen metabolism. In healthy volunteers, short-term infusion of triglycerides with heparin (to activate lipoprotein lipase and elevate the plasma FFA concentration) results in an increase in hepatic glucose output under conditions (hyperglycemia and somatostatin block of endogenous insulin response) mimicking the key features of diabetes [43]. When endogenous insulin is allowed to rise, or when exogenous insulin is administered, the stimulatory effect of triglyceride infusion on hepatic glucose release is easily overcome. Consistent with this, FFA infusion in healthy subjects augments hepatic gluconeogenesis but basal hepatic glucose production does not rise because of a reciprocal decrease in hepatic glycogenolysis [40,44].

In summary, long-chain FFA may regulate glucose production both by acting upon key enzymes of gluconeogenesis (through products of FFA oxidation) and by virtue of the substrate push of glycerol. In glucose-tolerant normal subjects, this regulatory mechanism is primarily operative when insulin secretion is not stimulated, that is, in the basal state. Insulin and the classic counterregulatory hormones—glucagon, cortisol, growth hormone (GH), catecholamines, and triiodothyronine (T_3)—form one of the best-described agonist–antagonist regulatory systems (Figure 14.3). Insulin is a potent, specific, and rapid-acting inhibitor of hepatic glucose production [12,45]. It restricts both glycogenolysis and gluconeogenesis, although with different dose–response characteristics, gluconeogenesis being less sensitive [24,46]. Moreover, by restraining lipolysis and proteolysis, insulin also reduces the delivery of potential glucose precursors (glycerol, amino acids) to the liver. In its capacity as the inhibitory signal for glucose release, insulin

is greatly favored by the anatomical connection between the pancreas and the liver, and secreted insulin reaches the liver at a concentration that in fasting humans is three- to fourfold higher than the peripheral (arterial) concentration [47]. Such portosystemic gradient is maintained by a high rate of insulin degradation by hepatic tissues (with a fractional extraction of about 50%). Thus, a small secretory stimulus to the β cell primarily serves to increase portal insulin levels, thereby selectively acting upon glucose production rather than also enhancing peripheral glucose utilization. In addition to short-circuiting the systemic circulation, pancreatic insulin release is potentiated by several gastrointestinal hormones (e.g. glucose-dependent insulinotropic polypeptide [gastric inhibitory polypeptide] and glucagon-like peptide 1). Therefore, anatomical and physiologic connections in the gut–liver–pancreas circle ensure that the primary station for the handling of foodstuff, the liver, is under close control by a nearby, well-informed unit, the β cell.

The anti-insulin hormones all counter insulin action on the liver by facilitating both glycogenolysis and gluconeogenesis. They do so, however, with different dose–response kinetics and time courses. Thus, glucagon and catecholamines act rapidly, while cortisol, growth hormone, and thyroid hormones (in that order) are involved in the long-term control of glucose release [48]. Glucagon plays a major part in the tonic support of hepatic glucose release: in humans suppression of glucagon release with preservation of basal insulin secretion causes a fall of glucose production of over one third [48]. The precise quantitative contribution of the other counterregulatory hormones system to the maintenance of basal glucose output has not been assessed. What has become established, however, is the strongly synergistic pattern of interaction between the anti-insulin hormones, such that their cumulative effect is larger than the sum of the individual effects [49,50]. This interaction also is expressed at the level of the components of glucose production, glycogenolysis and gluconeogenesis, as well as at the level of peripheral tissues (as discussed later in this chapter). An added feature of this homeostatic complex is the dual negative feedback between agonists and antagonists (Figure 14.3). Alpha cells and β cells "talk" to each other in the islets of Langerhans via paracrine influences (some of which may possibly be mediated by somatostatin). For example, insulin infusion *in vivo* reduces circulating glucagon levels by 20–30% even when changes in glycemia are prevented [51].

Another example is the direct modulation of β-cell secretion by catecholamines, with α-adrenergic stimulation (mostly, α-2) inhibiting and β-adrenergic stimulation increasing insulin secretion. It is noteworthy that in this control system a host of hormones is required to balance the action of only one agonist, insulin. This fact arises from the inhibitory nature of insulin's effect on the production of a fuel upon which brain cell viability depends in an obligatory manner.

Key points

- After a subject has fasted overnight, all of the glucose entering the circulation (at a mean rate of 12 μmol min^{-1} kg^{-1}, or about 220 g day^{-1}) derives from liver glycogenolysis and liver/renal gluconeogenesis, with approximately equal contributions from each metabolic pathway.

- Approximately 80% of endogenous glucose production is derived from the liver and 20% from the kidney.

- As fasting continues, glucose production becomes progressively more dependent on gluconeogenesis.

- Any given rate of glucose output is the net result of the inhibitory actions of insulin, hyperglycemia, parasympathetic nervous activity and substrate shortage on the one hand, and the stimulatory actions of counterregulatory hormones, hypoglycemia, sympathetic nervous activity, and gluconeogenic substrate load on the other. Among substrates, FFA have an added regulatory value for glucose output.

- Inappropriately elevated plasma insulin levels can be life-threatening in the fasting state by shutting off endogenous glucose supply to the brain. Insulin counterregulation, therefore, is entrusted to several hormones, providing both short-term and long-term control.

Glucose disposal

In the basal state, steady/near steady-state conditions prevail and whole-body glucose disposal equals endogenous (hepatic) plus renal glucose production. Data on the individual contribution of organs and tissues to total glucose uptake have been obtained in regional catheterization studies. In the case of the splanchnic area, in which glucose uptake and production both

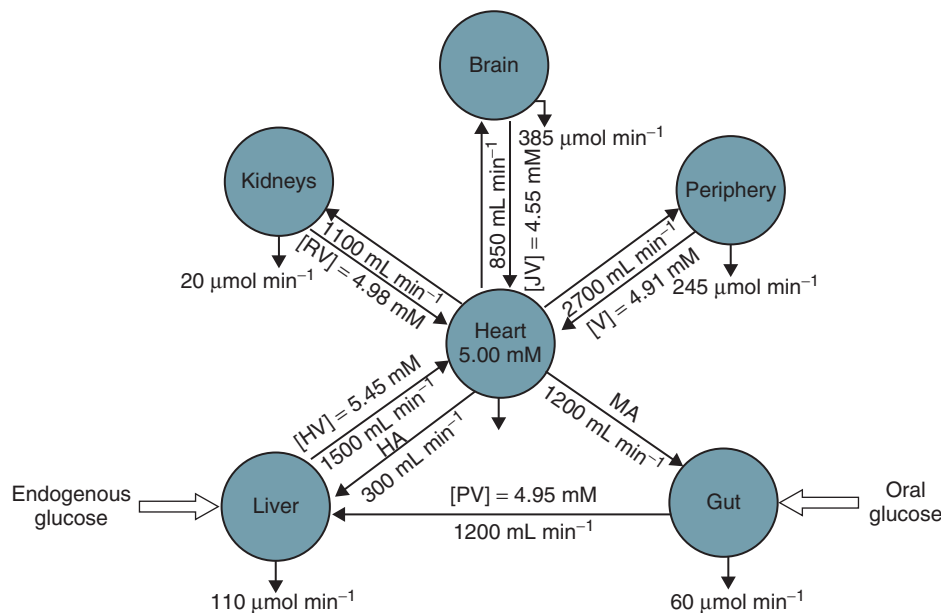
occur simultaneously, such data have been derived from the combined use of glucose tracers and indwelling catheters, as diagrammatically shown in Figure 14.1. By collating the available information, the organ-circulation model of Figure 14.5 can be drawn, in which steady-state inter-organ exchanges of blood and glucose, and regional glucose gradients, are calibrated at a rate of endogenous glucose release of 840 μmol min^{-1} (or 12 μmol min^{-1} kg^{-1} or 1.2 mol day^{-1}). In this model, it is seen that roughly 70% of basal glucose disposal takes place in insulin-independent tissues (brain, liver, kidney, intestine, erythrocytes). It can also be appreciated that the fractional extraction of glucose is quite low everywhere in the body (ranging from 1.7 to 2.8%) except in the brain (9%). If it is assumed that skeletal muscle (40% of body weight) receives 16% of cardiac output and is responsible for one quarter of overall glucose disposal (~245 μmol min^{-1}; Figure 14.5), then muscle glucose clearance averages 1.3 mL min^{-1} kg^{-1} of tissue. This value can be compared with those of other organs and tissues (Table 14.1) similarly obtained by dividing the organ glucose clearance by the estimated organ weight. In the rank of efficiency of glucose utilization in the basal state, resting muscle is last, being 10 times less active than the liver, and 50 times less avid than the brain. In tissues in which specific glucose clearance is already high (brain, liver, kidneys), the effect on glucose uptake of acutely raising plasma insulin levels above fasting values is small or absent, while in muscle glucose clearance can increase by a factor of 10 over the physiologic range of insulin concentrations. The intermediate position of heart muscle in the list is likely accounted for by its working state. As reviewed earlier, these


Figure 14.5 Schematic representation of organ glucose metabolism and blood flow in the basal or postabsorptive state. Average data compiled for healthy adults from the literature are indicated. "Periphery" encompasses all tissues other than liver, gut, kidneys, brain, and heart; "gut" includes organs (i.e., spleen, pancreas, etc.) draining their blood supply into the portal circulation. CA, carotid arteries; HA, hepatic artery; HV, hepatic vein; MA, mesenteric arteries; PV, portal vein; RV, renal veins; VA, vertebral artery. Organ blood flow is shown in mL min^{-1} and glucose fluxes in mg min^{-1} (umol min^{-1}).

Table 14.1 Regional glucose disposal in the basal state

Organ	Weight (kg)	Blood flow (l min^{-1})	Uptake (μmol min^{-1})	Extraction (%)	Clearance[a] (mL min^{-1} kg^{-1})
Brain	1.2	0.85	385	9.1	64
Liver	1.5	1.50	110	2.3	15
Kidneys	0.28	1.10	20	1.9	15
Heart	0.3	0.25	20	1.7	13
Gut	5.0	1.20	60	1.0	2.4
Muscle	28.0	1.05	245	3.5	1.3

[a]Organ clearance rate divided by organ weight.

characteristics can now be seen as the physiologic equivalent of the type and abundance of specific glucose transporters with which the various tissues are endowed. They also narrow the concept of an insulin-independent tissue: thus, raising the plasma insulin concentration does not accelerate glucose clearance. However, lowering insulin may reduce the efficiency of glucose removal, and even non-insulin-regulatable glucose transporters are subject to chronic regulation. In humans this has been verified for at least two insulin-independent tissues: the liver and the brain. For the former, selective hypoinsulinemia (induced with somatostatin and glucagon replacement) lowers splanchnic glucose uptake below the basal value in healthy volunteers [32] (Figure 14.4). For the latter, indirect calculations indicate that brain glucose clearance is reduced in type 2 diabetic patients with moderate fasting hyperglycemia [52]. The intracellular disposition of transported glucose can be studied by using glucose tracers, and then tracking down the appearance of the label in specific metabolic products, such as lactate (i.e., anaerobic glycolysis) or carbon dioxide (i.e., complete oxidation) (see earlier discussion). It should be noted that these techniques, even when correctly applied, provide estimates of the metabolic fate of *plasma* glucose, which is the labeled pool. If, for example, there should be direct oxidation of glycogen in muscle, the plasma glucose specific activity would miss it (because of the lack of G6Pase in muscle tissue). However, total carbon dioxide production, measured with indirect calorimetry, would include the oxidized glycogen together with all the other oxidized substrates. In general, measuring the exchange of oxygen and carbon dioxide with indirect calorimetry makes it possible to obtain estimates of net rates of substrate oxidation and also provides a close estimate of the rate of energy expenditure [53]. In the basal state and under ordinary nutritional circumstances, oxygen consumption averages ~250 mL min^{-1}, while carbon dioxide production is ~200 mL min^{-1}, that is, a whole body respiratory quotient of 0.8 (RQ = carbon dioxide production/oxygen consumption). Simple calculations [54] thus estimate whole-body net carbohydrate oxidation at about 60% of total glucose uptake. As the brain uses 46% of glucose turnover (Table 14.1) and readily oxidizes the transported sugar, it follows that three quarters (i.e., 46/60 = 77%) of basal glucose oxidation occurs in the

brain. Little is left for other tissues, which preferentially derive their metabolic energy from the oxidation of fatty substrates and return most of the glucose to the liver after conversion into lactate (Cori cycle). Skeletal muscle, for example, has a respiratory quotient of 0.75 and relies on fat oxidation for the production of 80% of the energy it needs in the resting state [55]. Thus, the basal state is characterized by parsimonious usage of glucose as fuel, which is selectively channeled to organs that cannot rely on alternative energy sources. Altogether over one half of total energy production (5 kJ min^{-1}) is generated via oxidation of fat, of which there are plentiful (~500 MJ) and almost unlimited stores (e.g. obesity). The role of insulin in maintaining this metabolic setup is permissive rather than determinant. Through a loose brake on lipolysis, insulin lets FFA override glucose in the competition between the two chief substrates, keeps glucose transport and metabolism in its own target tissues at a minimum, and restrains protein breakdown (which contributes only about 15% to energy metabolism). The part that counterregulation plays in basal glucose uptake is less well defined, but probably is centered upon maintenance of lipolysis, since all the anti-insulin hormones are more or less potent lipolytic stimuli.

Glucose cycles

After transport through the plasma membrane, glucose does not necessarily follow a straight path to its eventual fate — be it glycogen, pyruvate, or pentoses — but may go around in what are known as *futile cycles*. A metabolic futile cycle is one in which a precursor is converted into a product by a forward reaction, which is then reversed to resynthesize the precursor. In this way, no net product accumulates, but energy (ATP) is used. One example of a futile cycle, G6P to fructose-6-phosphate and back through the phosphoglucoisomerase reaction, has been discussed previously and can be measured as the difference between the turnover rate as estimated by ^{2}H and ^{3}H isotopes of glucose. Another example is glucose to G6P via glucokinase and back via G6Pase. In general terms, whenever bidirectional flux through a metabolic pathway is simultaneously operative, there exists a cycle, regardless of the number of intermediate reactions and regardless of whether one or more tissues are involved. In this sense, lipolysis in adipose tissue, followed by partial

reesterification of FFA in the liver, is a complete cycle. Another one is protein breakdown in skeletal muscle with reincorporation of amino acids into proteins in the liver. The negative connotation of futility has traditionally been reserved for those cycles that go on in the same cell. They are, however, anything but futile. As discussed by Newsholme [56], a metabolic cycle with an internal loop is the best kinetic stratagem to keep the enzymes of a dormant pathway at a minimum of activity, and to ensure a sensitivity gain for ready amplification of incoming signals. The ATP cost of these cycles is itself a means of increasing the efficiency of energy dissipation. The fact that the activity of these cycles is under hormonal control (e.g. catecholamines and thyroid hormones enhance the cycling rate) makes room for modulation; in this way, these cycles become components of facultative thermogenesis.

Key points

- Of fasting glucose uptake, 70% occurs in insulin-independent tissues, and two thirds of the glucose is completely oxidized. Much of this distribution is due to the obligatory use of glucose as fuel by the brain.

- In insulin-independent tissues, raising insulin does not stimulate glucose metabolism, but insulin lack may decrease the efficiency of glucose utilization (glucose clearance).

- Fat is the preferred substrate of insulin-dependent tissues in the basal state.

- Over 50% of basal energy production relies on fat oxidation.

The fed state

Introduction

The fed state is the absorptive period between meals. Carbohydrates are normally mixed with lipids and protein in the diet and make up 40–60% of the caloric content. Absorption of dietary carbohydrates is influenced by their chemical form (refined sugars or complex carbohydrates) and by other components of food. Furthermore, disposition of dietary carbohydrate is indirectly affected by fats and protein to the extent that these latter (i) compete with glucose as substrates, and (ii) interfere with glucoregulatory hormones by altering insulin secretion. To circumvent the difficulties of study of glucose ingestion, the regulation of glucose homeostasis during the fed state has classically been investigated with the use of intravenous glucose, which can be administered in formats more suitable for formal analysis.

Methods

Glucose can be injected intravenously as a single bolus (0.33 or 0.5 g [1.8 or 2.8 mmol] per kg of body weight) and the decline in plasma glucose concentration after the initial peak followed for 60–90 min (intravenous glucose tolerance test or IVGTT). Between 10–60 min, glycemia decreases approximately as a

single exponential function of time, and a decay constant (k value) can be calculated to estimate tolerance to intravenous glucose. The IVGTT has several drawbacks. First, the time course of glucose fall in reality is a multi-exponential function of time, so that the decay constant takes on different values according to which segment of the curve is used for analysis. Second, over the same time interval, different curves can have similar k values; for this reason, the area under the glycemic excursion is sometimes used instead of the k value. However, the area under the curve is also influenced by the volume into which the injected glucose is distributed. Third, and most important, the shape of the glucose curve is heavily affected by the endogenous insulin response to the acute hyperglycemia caused by the intravenous bolus. Such response is highly irregular, and after an initial peak proceeds in two or three smaller spikes tightly synchronized with similar glycemic spikes [57].

In general, in the presence of an intact feedback loop between glucose and insulin, glucose tolerance is the integrated outcome of multiple changes in the glucose as well as in the insulin system: distribution of the exogenous glucose, stimulation of peripheral glucose uptake by insulin and hyperglycemia, suppression of hepatic glucose output, and secretion, distribution and degradation of insulin. It is therefore not surprising that the information provided by an IVGTT is somewhat ambiguous, and that the test itself is neither very sensitive nor easily reproducible. A modern version of the IVGTT is that which interprets the changes in glucose and peripheral insulin concentrations (measured at frequent intervals following the bolus) on the basis of a "minimal" mathematical model of the glucose and insulin systems and their interactions [58]. The model generates a parameter reflecting the ability of hyperglycemia to stimulate insulin secretion, another parameter estimating the ability of insulin to stimulate glucose metabolism, and an index of the ability of glucose to promote its own disposal. Although attractive for its simplicity, the minimal model approach generally falls short of its ambitious goal, that is, to describe all aspects of glucose tolerance with a minimum of data. In particular, the minimal model does not work when the endogenous insulin response is scarce, for example in diabetic patients. The model is not minimal in that the data analysis requires a computer program that, like all package deals, deprives users of critical evaluation. Several updates of the technique have been devised. Labeled (tritiated or deuterated) glucose can be co-injected with cold glucose; appropriate model analysis of the tracer data makes it possible to dissect out the effects of insulin on the liver and on peripheral tissues [59]. Because of its complexity of use and interpretation, the latter remains a purely investigative tool.

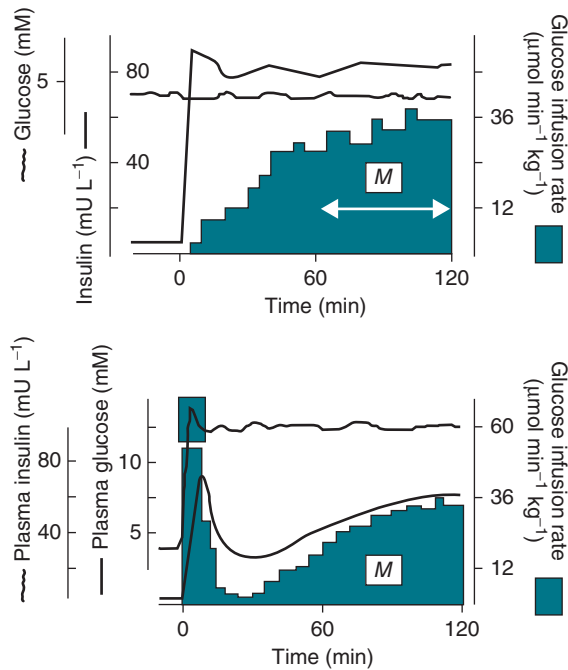
A secondary injection of exogenous insulin or tolbutamide has been used to circumvent the failure of the minimal model in case of insufficient endogenous insulin response [60]. A simple way to estimate whole-body sensitivity to insulin is to paralyze endogenous insulin release with a constant infusion of somatostatin (at a rate of 0.3–0.5 mg h^{-1}) while simultaneously infusing glucose (at a rate of 1.35 mmol min^{-1} m^{-2}) and regular


Figure 14.6 (top) Schematic representation of the euglycemic insulin clamp technique. See text for a detailed discussion. (bottom) Schematic representation of the hyperglycemic clamp technique. See text for a detailed discussion.

insulin (at a rate of $50\,mU\,min^{-1}\,m^{-2}$). With this technique (also known as the pancreatic suppression test) [61], steady hyperinsulinemia ($\sim 80\,mU\,L^{-1}$) is associated with a level of hyperglycemia that is inversely proportional to the ability of whole-body tissues to increase their glucose utilization in response to insulin. This test suffers from the fact that somatostatin inhibits the release of other glycoactive hormones (e.g. glucagon). With this limitation, however, the test is simple and reliable enough for clinical use. The glucose clamp technique has become the reference method to study glucose metabolism [62]. Figure 14.6 (top) exemplifies the euglycemic hyperinsulinemic version of the clamp technique. An exogenous infusion of regular insulin is started at time zero in a format comprising a prime followed by a constant infusion (usually at a rate of $1\,mU\,min^{-1}\,kg^{-1}$); such infusion quickly establishes a hyperinsulinemic plateau of about $60-70\,mU\,L^{-1}$. A few minutes after starting the insulin infusion, an infusion of glucose is begun at a rate which is adjusted every 5–l0 min on the basis of on-line plasma glucose measurements obtained with the same frequency. Over the second hour of a 2-h experiment, euglycemia in the face of constant hyperinsulinemia is maintained by an approximately constant glucose infusion, which in a healthy adult ranges between 20 and $50\,\mu mol\,min^{-1}\,kg^{-1}$ (a mean value is shown in the figure). Such a rate equals the overall rate of glucose uptake (also called *M* for metabolism) in a subject in whom endogenous glucose production is nil. Relative insulin insensitivity or insulin resistance is indicated by a low *M* value at comparable levels of glycemia and insulinemia. The technique

has the following advantages: (a) any preset combination of plasma glucose and insulin levels can be easily achieved; (b) the time course of insulin action can be determined with a time resolution of about 10 min; (c) hypoglycemia with its attendant counterregulatory hormonal response can be avoided; (d) other techniques, such as tracer glucose infusion, muscle biopsy, and indirect calorimetry, can be readily combined with a clamp protocol; (e) the interference of other hormones or substances with insulin action can be quantitated by co-infusing them during a clamp study; (f) high reproducibility.

Although computerized algorithms are available to run a clamp, manual operation with a minimum of experience does just as well. The major drawback of the euglycemic insulin clamp is the need to draw frequent blood samples from an arterialized vein (e.g. a heated wrist or hand vein). The hyperglycemic version of the glucose clamp (schematized in Figure 14.6, bottom) consists of acutely raising plasma glucose to any desired level, and then clamping it at that level with a variable infusion of exogenous glucose [62] (as in the euglycemic clamp version). The hyperglycemic step evokes an endogenous insulin response that typically is biphasic: an early output (of preformed hormone) that lasts 10–15 min, followed by a gradual, continuous rise in insulin levels (I), reflecting glucose-induced triggering and potentiation of β-cell secretory activity. By analogy with the euglycemic insulin clamp counterpart, the hyperglycemic clamp provides an *M* value, which represents the combined effect of endogenous hyperinsulinemia plus hyperglycemia on whole-body glucose disposal. The *M* value can be expressed per unit of insulin to provide an index of insulin sensitivity (*M*/I) that agrees closely with that derived from the euglycemic insulin clamp [62].

Intravenous glucose

In the presence of euglycemia, insulin displays a potent suppressive action on hepatic glucose production, such that portal insulin concentrations of less than $100\,mU\,L^{-1}$ abolish glucose entry into the circulation. Figure 14.7 shows a typical time course for endogenous glucose production following an acute increase in plasma insulin to levels of $60-70\,mU\,L^{-1}$ in a healthy subject. Dose–response curves relating calculated portal plasma insulin concentrations to suppression of glucose

production (Figure 14.8) indicate a half maximal effect at 30 mU L^{-1}, corresponding to increments in portal insulin in the range of only 5–10 mU L^{-1} [63]. Note that in its capacity of a glucose-producing organ the liver is very sensitive to insulin; physiologic hyperinsulinemia, on the other hand, does activate glucokinase, but the resulting increment in hepatic glucose uptake is very small [64]. Hyperglycemia induced by intravenous glucose administration strongly synergizes this inhibitory action of insulin on hepatic glucose release (see Figure 14.4): in normal adults, a rise in arterial plasma glucose levels of only about 2 mmol L^{-1} is sufficient to reduce glucose output promptly by over 80% [28]. Figure 14.8 also shows the dose–response of insulin-stimulated whole-body glucose disposal. The apparent maximum at euglycemia is in the order of 60 μmol min^{-1} kg^{-1} in healthy adult subjects, whereas the half-maximum lies around 70–110 mU L^{-1} of peripheral (systemic) plasma insulin concentrations [32]. A dose–response curve of similar shape is derived when progressively higher insulin doses are applied locally in forearm tissues, about 70% of which consists of skeletal muscle [65]. Extrapolating the latter data to total body muscle mass makes it possible to estimate that, with prevailing peripheral plasma insulin concentrations in the high physiologic range (60–90 mU L^{-1}), 50–70% of a total glucose flux of 30–40 μmol min^{-1} kg^{-1} is disposed of in muscle tissue. Obviously, this percentage increases further at still higher insulin levels as the contribution of insulin-independent tissues declines. The control of glucose production and utilization by insulin is dependent on both concentration and time. At any given hormone concentration, there is a finite time before the effect sets in and reaches its maximum. Such onset time is the sum of a circulatory delay (from arterial blood to cell surface) and a cellular lag (intracellular diffusion and effector activation). Similarly, insulin's effect is present for some time (offset) after the circulating concentration has returned to prestimulatory levels. Figure 14.9 shows the activation and deactivation times
of insulin calculated at euglycemia over a wide range of plasma hormone levels (up to 1000 mU L^{-1}) [66]. With the reservations inherent in the analysis of non-steady-state tracer data, these results provide evidence that activation and deactivation are inversely related to one another; thus, at higher insulin doses the effect is more rapid and takes longer to wane. Further, the relationship between onset and offset time is different for the liver (suppression of glucose release) and for peripheral tissues (stimulation of glucose uptake): at any insulin dose, the liver is activated more rapidly and more persistently. The latter phenomenon may have to do with the shorter diffusion time of blood-borne substances into highly perfused organs (1 mL min^{-1} per gram of tissue in the liver versus a corresponding value of 0.04 mL min^{-1} g^{-1} in resting skeletal muscle; Table 14.1). The inter-individual variation of insulin-stimulated glucose disposal is large, covering a five- to sixfold span even in relatively homogeneous groups of healthy subjects. Adipose mass and degree of physical fitness are powerful determinants of insulin sensitivity, in that weight loss and regular aerobic training are associated with demonstrable gains in insulin sensitivity. On the other hand, age, gender, distribution of body fat, diet, and menstrual phase are general physiologic covariates of insulin sensitivity. Evidence obtained in Pima Indians [67] demonstrates that genetic factors are at work in the distribution of insulin sensitivity in the population. By combining indirect calorimetry with dose–response studies using the clamp technique, it has been possible to quantitate the two major components of whole-body glucose disposal, that is, glucose oxidation and nonoxidative glucose disposal—the latter consisting of glycogen synthesis for the most part (>90%) and the remainder being net lactate production via aerobic glycolysis [68,69]. Figure 14.10 shows that the two daughter curves retain the sigmoidal shape of the mother curve but with distinctly different dose kinetics. Thus, glucose oxidation is more sensitive (lower apparent half-maximum) but saturates earlier (lower maximum) than glycogen synthesis; the latter behaves as a pathway with low sensitivity and high capacity.
Figure 14.10 Dose-response relationship between the plasma insulin concentration and total body glucose uptake, glucose oxidation, and nonoxidative glucose disposal in healthy subjects during a euglycemic insulin clamp. Source: Drawn from the data in Prager 1986 [66].

Skeletal muscle is the predominant site of insulin-mediated net glycogen synthesis; insulin also has a potent effect to augment hepatic glycogen synthesis although its contribution to total body glycogen synthesis is small compared to skeletal muscle. The increment in carbohydrate oxidation that follows systemic insulin administration occurs in muscle as well as other tissues including liver and adipocytes. Insulin inhibits lipolysis, reduces plasma FFA levels, and decreases and lipid utilization very effectively [63]. As shown in Figure 14.11 (top),

plasma FFA concentrations decline steeply in response to small increments in circulating insulin levels at euglycemia; this results from a drastic reduction in the rate of FFA appearance into the circulation. The consequence of the reduced availability of FFA is a parallel reduction in both FFA oxidation and nonoxidative FFA disposal, that is, reesterification (Figure 14.11, bottom). The reciprocal pattern of changes of glucose disposal/oxidation on the one hand, and lipid oxidation/utilization on the other, introduces the concept of substrate competition [70,71]. Glucose and long-chain FFA are the first and best-known example of substrates in mutual competition for use by insulin-dependent tissues as fuels. Physiologically, a rise in plasma glucose concentration increases the rate of glucose uptake into cells by mass action; the resulting increase in the generation of α-glycerolphosphate during anaerobic glycolysis supplies the substrate for augmented reesterification of tissue FFA, thereby limiting their release into the blood stream. This effect is reinforced by the glucose-induced rise in insulin, which further reduces the supply of lipid substrates by directly inhibiting lipolysis. This glucose-on-FFA feedback is balanced by an FFA-on-glucose negative feedback. A rise in FFA availability enhances lipid oxidation and restrains pyruvate oxidation (at the pyruvate dehydrogenase step). This sequence of biochemical events and the intracellular signals that trigger it were elucidated by Randle and coworkers in an elegant series of experiments in

rat hearts and diaphragms [70]. In the human, experimental elevations in FFA concentrations inhibit insulin-mediated glucose disposal in a fashion that is both dose-dependent [72] and time-dependent [73]. The insulin dose–response curves for glucose oxidation and glycogen synthesis are both shifted downwards during concomitant administration of an intra-venous lipid load (Figure 14.12), providing evidence that an excess of lipid (FFA) supply inhibits not only glucose oxidation but also glycogen synthase [42] and glucose transport [74]. The extent to which insulin action in target tissues is direct rather than mediated by shifts in substrate supply can be appreciated by comparing systemic with local insulin administration. When infused intra-arterially into the forearm, insulin does not alter the circulating substrate supply, in that neither FFA nor glucose levels change in the arterial blood re-circulating to the forearm tissues. Under these conditions, insulin stimulates forearm glucose uptake and lactate release, but induces only minimal changes in the local respiratory quotient (0.76). This indicates that the forearm tissues continue to rely mostly on lipid oxidation for energy production, and that the vast majority of insulin-stimulated glucose uptake is channeled to

glycogen [55]. In contrast, when comparable hyperinsulinemia is created by systemic insulin administration (with maintenance of euglycemia), the leg respiratory quotient increases from 0.74 to almost 1.00, that is, glucose oxidation increases while lipid oxidation is markedly depressed [75]. In addition to substrate competition (Randle cycle), it is now recognized that FFA inhibit insulin-stimulated glucose metabolism by multiple other mechanisms. Following their entry into the cell, FFA are converted to their FACoA derivative. Long-chain FACoA inhibits the insulin-signal transduction system by causing serine phosphorylation of the insulin receptor and insulin receptor substrate (IRS)-1 (see subsequent discussion) [72]. LC-FACoA also have independent effects to inhibit the glucose transport system (GLUT4), glucose phosphorylation (hexokinase), and glycogen synthase [42,74,76,77]. Elevated intracellular levels of LC-FACoA are associated with increased concentrations of diacylglycerol (DAG) and ceramides which also cause serine phosphorylation of the insulin receptor and IRS-1, resulting in impaired insulin signaling and insulin resistance [78–80]. Collectively, these negative effects of LC-FACoA, DAG, and ceramides on insulin-stimulated glucose metabolism have been referred to as lipotoxicity [81]. Amino acids also can enter a competition cycle with glucose, although somewhat less effectively than FFA. Increased amino acid provision enhances glucose production under conditions of insulin deficiency or resistance, and limits glucose utilization in the insulinized state [60]. Furthermore, raising FFA has a hypoaminoacidemic effect in humans [82].

In summary, each of the three major substrates, if present in excessive amounts (whether by endogenous production or exogenous administration), can lower the level of the other two by stimulating insulin release. In this capacity, glucose is obviously favored, being a much more potent secretagogue than fat or amino acids. In addition, multiple substrate effects (not mediated by changes in insulin release) participate in the regulation of the substrates themselves: high FFA and amino acids raise glucose, while high FFA lower amino acids [83] (Figure 14.13).
Figure 14.13 The glucose-FFA-amino acid cycle. Because glucose, FFA, and amino acids are all insulin secretagogues, isolated increases of each of them lower the circulating levels of the other two via hyperinsuline-mia (inner ring). By substrate competition (outer ring), an increased supply of either FFA or amino acids will spare glucose. In addition, FFA have a hypoaminoacidemic effect of their own. See text for a detailed discussion.

Cellular, biochemical, and molecular mechanisms of insulin action (see also Chapter 12)

Insulin receptor/insulin receptor tyrosine kinase

The insulin receptor is a glycoprotein consisting of two α subunits and two β subunits linked by disulfide bonds and expresses insulin-stimulated kinase activity directed towards its own tyrosine residues [12,84–87]. Insulin receptor phosphorylation of the α subunit, with subsequent activation of insulin receptor tyrosine kinase, represents the first step in the action of insulin on glucose metabolism. Insulin receptors devoid of tyrosine activity are completely ineffective in mediating insulin stimulation of cellular metabolism. Mutagenesis of any of the three major phosphorylation sites (at residue 1158, 1163, and 1162) impairs the insulin receptor kinase activity, and this is associated with a marked decreased in the acute metabolic and growth-promoting effects of insulin [12,86–88].

Insulin receptor signal transduction

After activation, insulin receptor tyrosine kinase phosphorylates specific intracellular proteins, of which at least nine have been indentified (Figure 14.14). Six of these belong to the family of insulin-receptor substrate (IRS) proteins; IRS-1, IRS-2, IRS-3, IRS-4, IRS-5, IRS-6 (the others include Shc, Cb1, Gab-1, p60 [dok], and APS). In muscle, IRS-1 serves as the major docking protein that interacts with the insulin receptor tyrosine kinase and undergoes tyrosine phosphorylation in regions containing amino acid sequence motifs (YXXM or YMXM) that, when phosphorylated, serve as recognition sites for proteins containing src-homology 2 (SH2) domains. Mutation of these specific tyrosines severely impairs the ability of insulin to stimulate glycogen synthesis, establishing the important role of IRS-1 in insulin signal transduction [12,84–88]. In liver, IRS-2 serves as the primary docking protein that undergoes tyrosine

phosphorylation and mediates the effect of insulin on hepatic glucose production, gluconeogenesis, and glycogen formation. In adipocytes, Cb1 is phosphorylated after its interaction with the insulin receptor tyrosine kinase and is required for stimulation of GLUT4 translocation [2].

In muscle, the phosphorylated tyrosine residues on IRS-1 mediate an association between the SH2 domain of the 85-kDa regulatory subunit of PI3K, leading to activation of the enzyme (Figure 14.14). PI3K is a heterodimeric enzyme composed of an 85-kDa regulatory subunit and a 110-kDa catalytic subunit. The latter catalyzes the 3′-phosphorylation of phosphatidylinositol (PI) in the plasma membrane glycolipids, thereby converting PI4,5-bisphosphate to PI3,4,5-triphosphate and PI4-phosphate to PI3,4 biphosphate. $PI(3,4,5)P_3$ and $PI(3,4)P_2$ lead to the stimulation of glucose transport [12,84–88]. Activation of PI3K by phosphorylated IRS-1 also stimulates glycogen synthase, via a process that involves activation of protein kinases B/Akt and subsequent inhibition of kinase such as GSK3 and activation of protein phosphatase-1 [89]. Insulin stimulates glycogen synthesis by simultaneously activating glycogen synthase and inhibiting glycogen phosphorylase [89,90] (Figure 14.15). The effect of insulin is mediated via the PI3K pathway, which inactivates phosphatases, particularly PP-1. It is believed that PP-1 is the primary regulator of glycogen metabolism [84,89–91]. In skeletal muscle, PP-1 associates with a specific glycogen binding regulatory subunit, causing dephosphorylation (activation) of glycogen synthase. PP-1 also phosphorylates (inactivates) glycogen phosphorylase. The precise steps that link insulin receptor tyrosine kinase/PI3K activation to stimulation of PP-1 have yet to be defined. Akt has been shown to phosphorylate and thus inactivate GSK3. This decreases glycogen synthase phosphorylation, leading to activation of the enzyme. From the physiologic standpoint, it makes sense that activation of glucose
Figure 14.14 Schematic representation of the insulin receptor and the cascade of intracellular signaling molecules that have been implicated in insulin action. See text for a more detailed discussion.
Figure 14.15 Schematic representation of the control of glycogen synthesis and breakdown. Sites of insulin regulation are indicated. See text for a detailed discussion.

transport and glycogen synthase should be linked to the same signaling mechanisms to provide a coordinated and efficient stimulation of intracellular glucose metabolism.

Glucose transport

Activation of the insulin signal transduction system in insulin target tissues leads to the stimulation of glucose transport. The effect of insulin is brought about by the translocation of a large intracellular pool of GLUTs (associated with low density microsomes) to the plasma membrane [1,2,84,92]. As discussed earlier, there are five major, different facilitative GLUTs with distinctive tissue distributions. GLUT4, the insulin regulatable transporter, is found in insulin-sensitive tissues (muscle and adipocytes), has a K_m of ~5 mmol L^{-1}, which is close to that of the fasting plasma glucose concentration and is associated with HK-II [19,93]. In adipocytes and muscle, its concentration in the plasma membrane increases markedly after exposure to insulin, and this increase is associated with a reciprocal decline in the intracellular GLUT4 pool. Acute physiologic hyperinsulinemia does not increase the total number of GLUT4 in muscle, even though several studies have demonstrated an increase in muscle GLUT4 mRNA. Using a novel isotopic dilution technique, the *in vivo* dose–response curve for the action of insulin on glucose transport in human forearm skeletal muscle has been described [94,95] (Figure 14.16). GLUT1 represents the predominant GLUT in the insulin-independent tissue (brain and erythrocytes). It is located primarily in the plasma membrane, where its concentration changes little after the addition of insulin. It has a low K_m (~1 mmol L^{-1}) and is well suited for its function, which is to mediate basal glucose uptake. It is found in association with HK-I [19,93,96]. GLUT2 predominates in the liver and pancreatic β cells, where it is found in association with a specific HK, HK-IV. In the β cell, HK-IV is referred to as glucokinase [97]. GLUT2 has a high K_m (~15–20 mmol L^{-1}) and, as a consequence, the glucose concentration in cells expressing this transporter increases in direct
Figure 14.16 Insulin-dose response curve for inward (Kin) and outward (Kout) rate constants for the transmembrane transport of 3-O-methyl-glucose in forearm skeletal muscle at different plasma insulin concentrations. *$p < 0.05$ vs. basal, **$p < 0.01$ vs. basal. proportion to the increase in plasma glucose concentration. This characteristic allows these cells to behave as glucose sensors.

Glucose phosphorylation (Table 14.2)

Glucose phosphorylation and glucose transport are tightly coupled phenomena. Isoenzymes of HK (HK-I to HK-IV) catalyze the first committed intracellular step of glucose metabolism, the conversion of glucose to G-6-P [19,93,96,97]. HK-I, HK-II, HK-III are single-chain peptides that have a number of properties in common, including a very high affinity for glucose and product inhibition by G-6-P. HK-IV, also called glucokinase, has a lower affinity for glucose and is not inhibited by G-6-P. Glucokinase (HK-IVB) is believed to be the glucose sensor in the β cell, whereas HK-IVL plays an important role in the regulation of hepatic glucose metabolism.

In human skeletal muscle HK-II transcription is regulated by insulin [98]. HK-I is also present in human skeletal muscle but is not regulated by insulin. In response to physiologic euglycemic

Table 14.2 Classification of glucose transporter and hexokinases in various tissues

Organ	Glucose transporter	Hexokinase Coupler	Classification
Brain	GLUT1	HK I	Glucose dependent
Erythrocyte	GLUT1	HK I	Glucose dependent
Adipocyte	GLUT4	HK II	Insulin dependent
Muscle	GLUT4	HK II	Insulin dependent
Liver	GLUT2	HK IV$_L$	Glucose sensor
B-cell	GLUT2	HK IV$_B$	Glucose sensor
Gut	GLUT3-Symporter		Sodium dependent
Kidney	GLUT3-Symporter		Sodium dependent

hyperinsulinemia, HK-II cytosolic activity, protein content, and mRNA levels increase by 50% to 200% in healthy subjects [98] and this is associated with the translocation of HK-II from the cytosol to the mitochondria [99]. In contrast, insulin has no effect on HK-I activity, protein content, or mRNA levels.

Glycogen synthesis (Figure 14.15)

After glucose enters the cell and is phosphorylated, it can either be converted to glycogen or enter the glycolytic pathway. Of the glucose that enters the glycolytic pathway, approximately 90% is oxidized. In the low physiologic range of hyperinsulinemia, glycogen synthesis and glucose oxidation are of approximately equal quantitative importance. With increasing plasma insulin concentrations, glycogen synthesis becomes predominant [63,68]. Glycogen synthase is the key insulin-regulated enzyme that controls the rate of muscle glycogen formation [100–102]. Insulin enhances glycogen synthase activity by stimulating a cascade of phosphorylation-dephosphorylation reactions that ultimately lead to the activation of PP-1 (also called glycogen synthase phosphatase). The regulatory subunit (G) of PP-1 has two serine phosphorylation sites, called site 1 and site 2. Phosporylation of site 2 by cyclic adenosine monophosphate-dependent kinase (PKA) inactivates PP-1, while phosphorylation of site 1 by insulin activates PP-1, leading to the stimulation of glycogen synthase. Phosphorylation of site 1 of PP-1 by insulin in muscle is catalyzed by insulin-stimulated protein kinase-1, which is part of a family of serine/threonine protein kinases termed ribosomal S6-kinases. The effect of insulin on glycogen synthase gene transcription and translation *in vivo* has been studied by employing the euglycemic insulin clamp in combination with muscle biopsies. Most studies have shown that insulin does not increase glycogen synthase mRNA or protein expression in human muscle *in vivo*. Rather, insulin converts the inactive (phosphorylated) form of glycogen synthase to the active (dephosphorylated) form of the enzyme [56–58].

Glycolysis/glucose oxidation

Glucose oxidation accounts for approximately 90% of total glycolytic flux, while anaerobic glycolysis accounts for the
Figure 14.17 Schematic representation of the control of pyruvate dehydrogenase. Sites of insulin regulation are shown. See text for a detailed discussion. NAD$^+$, oxidized nicotinamide adenine dinucleotide; NADH, reduced nicotinamide adenine dinucleotide; PDH, pyruvate dehydrogenase.

other 10% [69]. Two enzymes, PFK and PDH, play central roles in the regulation of glycolysis and glucose oxidation, respectively. PFK represents a key functional step in control of glycolysis [103,104]. However, insulin does not exert any direct effect on this enzyme, which is primarily regulated by the energy (ATP) and fuel (citrate, acetyl-CoA) status of the cell. However, insulin indirectly stimulates PFK by increasing fructose-2,3-bisphophate, a potent activator of PFK. Insulin has no effect on muscle PFK activity, mRNA levels, or protein content in nondiabetic individuals [105]. Insulin also regulates flux through glycolysis by increasing the activity of the multienzyme complex, PDH [106,107]. This enzyme is activated by insulin, which stimulates PDH phosphatases, thus converting the enzyme from its inactive phosphorylated form to its active dephosphorylated form (Figure 14.17). The PDH complex enzyme is also inhibited by its products, acetyl-CoA and reduced nicotinamide adenine dinucleotide (NADH).

Oral glucose

At any point in time, the glycemic response to exogenous glucose is the balance between the rate at which glucose appears in the systemic circulation (from oral as well as endogenous sources) and the rate at which glucose is disposed of. Oral glucose appearance in the peripheral circulation depends on: (a) the rate at which the gastric contents are passed on to the small intestine; (b) the rate of intestinal glucose absorption; (c) the extent of gut glucose utilization; (d) the degree of hepatic glucose trapping; and (e) the dynamics of glucose transfer through gut, liver, and posthepatic circulation on to the right heart. The contribution of endogenous glucose to the glycemic response to feeding depends on the extent and rate of change of hepatic glucose production. Finally, glucose disposal depends on changes in the pattern of hormonal stimuli and substrate availability.

Being a summation phenomenon, the response to oral glucose explores the whole of glucose tolerance, not the individual contribution of the various components. The rate-limiting step in the transfer of ingested glucose from the stomach to the liver is

the rate of gastric emptying. This depends on the volume, temperature, and osmolarity of the glucose solution in the case in which glucose alone is ingested. Glucose absorption through the intestinal lining cells is rapid and efficient, the capacity of the whole small intestine being far in excess of ordinary needs. The presence of sodium chloride in the glucose drink enhances glucose absorption. Glucose utilization by intestinal tissues is small when glucose is presented on the vascular side, that is, when there is no oral glucose (Table 14.1).

The possibility also exists that systemic hyperglycemia and/or hyperinsulinemia may interfere with intestinal glucose absorption. Experimentally induced hyperglycemia impairs gastric motility and slows down gastric emptying, thereby delaying the absorption of oral antidiabetic drugs.

Glucose uptake by the liver is stimulated by portal hyperglycemia (see later), but traversing the hepatic space is unlikely to significantly delay the appearance of oral glucose in the systemic circulation. On the whole, the dynamics of oral glucose appearance are essentially driven by gastric emptying, while intestinal transit, crossing of the mucosa to enter portal blood, and transhepatic passage together introduce only a small time delay. In other words, if neither gut nor liver tissues used glucose, the time course of oral glucose appearance would only follow gastric emptying, with a time shift of a few minutes. For this reason, the absorption step is a major component of the shape of the glycemic response to glucose. Figure 14.18 shows the pattern of appearance of ingested glucose in the systemic circulation in healthy individuals, as reconstructed by a double tracer technique [108]. Glucose arrival peaks within 30–45 min, declines slowly thereafter, and is still significantly above zero 210 min after glucose ingestion. A secondary rise in oral glucose appearance is sometimes seen between 2 and 3 h after ingestion. Figure 14.18 also shows the time course of suppression of endogenous glucose release by oral glucose. A sustained nadir between 45 and 135 min is followed by a slow return toward fasting rates; hepatic glucose production is still significantly inhibited 210 min after the glucose challenge. Overall suppression of endogenous glucose production during 3–4 h after ingestion averages 50%, surprisingly less than what would be expected on the basis of the combined portal hyperglycemia and hyperinsulinemia (see Figure 14.4). Relative to intravenous glucose/ insulin administration, glucose ingestion evidently reinforces counterregulatory influences which keep liver glucose outflow open.

In Figure 14.19 the observed arterial plasma glucose concentration is broken down into the component contributed by oral glucose appearance and that provided by hepatic glucose production. While the resemblance of oral Ra to the plasma glucose curve is evident (especially during the first 60–90 min), less appreciated is the fact that absorption is still incomplete 3–4 h after ingestion. Figure 14.18 depicts the time course of total glucose disposal (Rd) following oral glucose: with a lag of some 30 min, glucose uptake is stimulated by 50–110% throughout the period of observation. Hyperglycemia contributes more to
Figure 14.18 Rates of appearance of oral (a) and endogenous (b) glucose following the ingestion of $1\,\mathrm{g\,kg^{-1}}$ of glucose in health subjects. Total body rate of glucose disappearance is shown in (c).

whole-body glucose disposal during the first half of the test; thereafter, hyperinsulinemia predominates. Oral glucose elicits vasodilation of the splanchnic vascular bed; this, too, is a change that persists for at least 4 h [109]. Thus, both the metabolic and the hemodynamic perturbations induced by oral glucose extend beyond the time of return of plasma glucose to pre-ingestion levels. The tissue destination of absorbed glucose has been the subject of intense investigation. While the liver classically was reputed to be responsible for the eventual disposal of the majority of oral glucose [109], the weight of more recent evidence [33,36,110] favors the view that peripheral tissues are responsible for between one half and two thirds of glucose uptake, while the splanchnic tissues account for the remainder.

A robust insulin secretory response directs more posthepatic glucose to the periphery, while a large increase in splanchnic blood flow increases the delivery of incoming sugar to the liver. In humans, for example, a glucose drink sipped over 3.5 h rather than swallowed in one bolus generates the same overall glucose curve but a 50% smaller endogenous insulin response [111].

The route of administration seems to influence the metabolic fate of glucose [33,36,113,114], in that the portosystemic glucose gradient per se enhances liver glucose uptake independently of portal glycemia and total glucose delivery to the organ [33,36,112,113] (as previously discussed).
Figure 14.19 Separation of actual arterial plasma glucose concentration into its components contributed by endogenous and oral glucose (reconstructed by tracer analysis).

Limited information is available on the intracellular fate of ingested glucose. While glucose oxidation in the brain continues unabated during the absorptive period, some 50% of the glucose taken up by peripheral tissues (muscle) is oxidized, the remainder being stored as muscle glycogen or as lactate in the lactate pool [114]. During absorption, there is an increase in lactate release by both the splanchnic area as a whole and the intestine [28–30]. In the latter, it has been estimated that some 5% of the ingested load is converted into three-carbon precursors of glucose (lactate, pyruvate, and alanine) and passed on to the liver [28,115]. The net release of lactate by the splanchnic area indicates that the sum of hepatic lactate production and gut lactate formation exceeds hepatic lactate extraction. Liver glycogen formation during absorption of oral glucose certainly occurs both directly from glucose and indirectly via gluconeogenesis. The relative contribution of the direct versus indirect pathway to hepatic glycogen synthesis is somewhat uncertain owing to methodological difficulties. Current data [116] suggest that gluconeogenesis participates in liver glycogen repletion to a lesser extent in humans than in rats [117,118].

Following glucose ingestion, the plasma insulin response is two- to threefold greater than that observed when the same glucose profile is created by intravenous glucose [119]. This incretin effect is due to the release of glucagon-like peptide (GLP)-1 and glucose-dependent insulinotropic polypeptide (GIP), which are secreted by the K cells of the early small intestine and L cells of the distal small bowel/large intestine [119,120]. GLP-1 and GLP are released within 2–3 min following glucose ingestion. Since gastric emptying takes 10–15 min to begin, it is clear that the nutrients cannot have reached the duodenum and certainly not the large bowel. The release of GLP-1 and GIP is mediated via neural connections to the brain and back via the vagus nerve [121]. Although activation of the neural pathway within minutes leads to the release of GLP-1 and GIP, insulin secretion is not increased since the stimulatory effect of GLP-1 and GIP on the β cell is glucose dependent and only occurs when gastric empting begins and the plasma glucose concentration rises. Approximately half of all insulin that is secreted in response to oral glucose is dependent upon GLP-1/GIP in healthy subjects. A direct effect of GLP-1 to augment hepatic glucose uptake, beyond its stimulatory effect on insulin secretion, has been proposed [122]. The inhibition of glucagon secretion and simultaneous stimulation of insulin secretion conspire to suppress hepatic glucose production. GLP-1 also has a direct effect on the liver to enhance hepatic glucose uptake [123].

Key points

- The liver (hepatic glucose production) is more sensitive to the inhibitory action of insulin than are peripheral tissues (glucose uptake) to the stimulatory action of the hormone.
- Insulin action on glucose metabolism is both direct (enhancement of glucose transport, glycolytic breakdown, and incorporation into glycogen) and indirect (inhibition of lipolysis, lipid oxidation, and protein degradation).
- In insulin-sensitive tissues, the three major substrates (glucose, FFA, amino acids) are in competition with one another.
- The counterregulatory hormones oppose both the direct and the indirect actions of insulin on glucose disposal.
- Physiologic hyperinsulinemia activates the insulin signal transduction system leading to a coordinated increase in glucose transport/phosphorylation, glycogen synthesis, and glucose oxidation.
- The shape of the oral glucose tolerance curve is dominated by absorption processes, especially early after ingestion. Later on, insulin action prevails.
- Insulin controls oral glucose tolerance by suppressing endogenous glucose production and promoting glucose uptake into muscle. Hyperglycemia enhances splanchnic glucose uptake.
- GLP-1 directly, and indirectly by increasing insulin and inhibiting glucagon, augments hepatic glucose uptake and inhibits hepatic glucose production.

Measuring insulin action *in vivo*

Richard N. Bergman and Marilyn Ader

Cedars-Sinai, Los Angeles, CA, USA

Key points

- Insulin resistance is a risk factor for many diseases including diabetes.
- The glucose clamp remains the most straightforward and accurate method, but it must be done carefully.
- The minimal model method is accurate, and also yields indices of insulin response and metabolic clearance rate of insulin, and glucokinase activity.
- Surrogate measures of insulin resistance, HOMA and QUICKI, are not accurate with even a moderate depression of β-cell function.
- OGTT measures can be used, but are also not independent of changes in glucose absorption, insulin secretion, and insulin clearance.
- There is a need for more accurate noninvasive measures of insulin action.

Historical perspective

The heralded isolation of insulin in Toronto in 1921 was followed immediately by treatment of diabetes. It soon became clear that while insulin was effective in regulating the blood glucose levels in most patients, there were some subjects in whom insulin appeared to be ineffective [1,2]. This lack of insulin effect was termed "insulin resistance" as early as 1925 [3]. In a remarkable early study, Bainbridge observed that rats and mice, fed a carbohydrate-free, excess fat diet, developed a high degree of resistance to insulin. In 1936, Himsworth noted that the effect of insulin injection was less pronounced in obese subjects and subjects with "mild" diabetes [4]. He suggested that obesity and diabetes are related to insulin resistance [5] and that insulin sensitivity could be increased by high carbohydrate, low fat diets [6]. However, lack of ability to measure insulin directly made the interpretation of Himsworth's elegant studies difficult in terms of insulin action per se. Introduction of the radioimmunoassay

by Berson and Yalow provided the first compelling evidence for the existence of insulin resistance. These authors were aware that higher insulin after oral glucose implied insulin resistance, and suggested insulin resistance in obese patients, and patients with "maturity onset" (type 2) diabetes [7,8]. However, absent a direct assessment of insulin resistance, the putative role of this presumed defect in type 2 diabetes (T2DM) remained controversial. Adding to the controversy was Kipnis' elegant demonstration of an insulin secretory defect in type 2 patients. Kipnis reported a diminished plasma insulin response to a *matched* plasma glucose pattern in type 2 diabetic patients compared to nondiabetic patients [9]. Thus as of 1970, supportive evidence existed suggesting a defect in β-cell function was responsible for "maturity onset" diabetes; *au contraire*, insulin resistance could likewise be implicated.

Opening the loop: the pancreatic suppression test

Controversy regarding insulin resistance in T2DM was due to the "closed-loop" feedback system, which regulates the blood glucose concentration (Figure 15.1). In normal individuals, ingestion of a meal increases glucose and other secretagogues, including GIP and GLP-1, which act in concert to stimulate insulin secretion. Hyperinsulinemia in turn acts to renormalize the plasma glucose level by suppressing glucose production and increasing glucose utilization. In the presence of insulin resistance per se, the elevated insulin will be less able to normalize glucose, therefore resulting in a secondary stimulus to the β cells and relative hyperinsulinemia. In fact, postprandial hyperinsulinemia was considered by Berson and Yalow to be the signature for insulin resistance [7,8]. However, β-cell oversecretion could also account for postprandial hyperinsulinism. In fact, some investigators have suggested that hyperinsulinism itself is the primary event in the development of T2DM [10]. Because of the closed-loop relationship between insulin secretion and insulin action it is problematic to infer the existence of insulin resistance directly from a "closed-loop" procedure such as the oral glucose

Insulin producing and insulin degrading tissues

Plasma glucose

Plasma insulin

Glucose producing and glucose utilizing tissues
Figure 15.1 Closed-loop relationship between insulin and glucose.

tolerance test (OGTT), although this approach has become more widely used lately (see later, [11,12]). Equally important, it appeared it was not possible to assign a quantitative value to insulin resistance based solely on the closed-loop response to oral glucose.

Shen and Reaven demonstrated definitively the existence of insulin resistance in patients with T2DM [13–15]. These investigators intervened experimentally to interrupt the closed-loop. They made the β cells relatively unresponsive to increasing ambient blood glucose. Initially this was done with epinephrine [14,15] and later with somatostatin [16,17]. Infusing a compound that renders the β cells unresponsive during glucose infusion, the resultant steady-state glucose concentration "SSPG" is suggestive of insulin resistance. They reported that SSPG was higher in obesity, but highest in T2DM [18,19]. Thus, Reaven and colleagues provided persuasive evidence that insulin resistance existed concomitant with T2DM. However, the existence of insulin resistance did not rule out the possibility that β-cell deficiency could also play a role in the pathogenesis of T2DM. Also, SSPG, while indicative of apparent insulin resistance, does not represent a quantitative *in vivo* index of insulin sensitivity of the tissues. In addition, SSPG is highly dependent on utilization of glucose at high concentrations independent of the ambient insulin level ("glucose effectiveness," cf. [20]). In fact, the debate regarding the relative importance of resistance versus insulin secretory defects in T2DM raged for several decades beyond the introduction of the pancreatic suppression test, which confirmed the insulin resistant state [21–25].

Qualitative versus quantitative

Often it is not sufficient to establish whether insulin resistance exists, relative to a normative population. Much more common is the need to *measure* insulin resistance, that is, to attach a *number* to it. A drawback of the qualitative resistance concept is that (as discussed earlier) virtually complete insensitivity to insulin can exist ("infinite insulin resistance"). It is much more practical to think in terms of "insulin sensitivity", where the latter concept is the inverse of resistance. Thus, insulin sensitivity determined by whatever method may have a minimum value near

zero (total resistance), and values may extend to a finite number representing great sensitivity to the hormone. The first *quantitative* method to measure insulin sensitivity was originated by the late Ruben Andres, and it is still called the "euglycemic glucose clamp" [26].

The glucose clamp

Rather than using exogenous agents that suppress β-cell insulin secretion, the glucose clamp uses external feedback control to "open the loop" between insulin secretion and sensitivity (Figure 15.2). The glucose clamp is a powerful and widely used method to attain a quantitative measure of insulin sensitivity, and has been applied in many hundreds of experimental studies.

Performing the clamp

DeFronzo and colleagues published the most widely applied clamp methodology [26,27]. In the simplest "euglycemic" manifestation, catheters are inserted in the right and left arms of the subject, and basal samples are collected, after which insulin is infused intravenously at a constant rate. The dose of insulin has varied widely [26–34]; however, the usual dose is $40\,mU\,min^{-1}\,m^{-2}$. Infusing insulin would normally lower the blood glucose; however, the lowering is prevented by infusing glucose concomitant with the insulin infusion. It is not possible a priori to know the rate of glucose infusion to prevent insulin from changing; therefore, a separate *external* feedback loop is established wherein glucose is measured frequently (usually every 5 min) and infusion rate is chosen to attempt to keep the plasma glucose concentration from changing.

In normal subjects plasma glucose concentration is usually "clamped" at or near 5 mM. Clearly, if a subject is extremely insulin resistant (sensitivity ∼ 0), very little exogenous glucose would be needed to be infused despite increased insulin; if a

subject is very sensitive to insulin, the needed exogenous glucose infusion rate will be substantial. The rate of glucose infusion is considered a reflection of insulin sensitivity. Insulin sensitivity is normalized to body size in some manner—either per kg body weight [35], per surface area [36,37], or per unit fat-free mass [38,39].

It is not a simple matter to determine in real time the exact glucose infusion rate needed to keep glucose at a predetermined "target" value. There have been numerous attempts to automate the external feedback loop, which includes the glucose measuring device as well as the glucose infusion device. Algorithms have been made available to calculate glucose infusion rate independently [26,40–42]. These algorithms have the advantage of objectivity; however, in most laboratories even today exogenous glucose infusion rate is determined at the bedside by a trained individual. The need for frequent monitoring of the blood glucose, and the need for a practiced individual to control the glucose infusion rate as a function of time, renders the glucose clamp method labor intensive and costly. Although providing an accurate measure of insulin sensitivity, under most circumstances three trained individuals are needed to carry on a safe and effective glucose clamp experiment on a human subject.

Components of insulin action calculated from the euglycemic clamp

Under fasting conditions in normal individuals, the blood glucose is determined by a balance between endogenous glucose production by the liver (and kidneys) and glucose uptake by insulin-independent (brain, red blood cells, gut) and insulin-dependent tissues (skeletal muscle, heart, adipose). Infusing insulin lowers the blood glucose both by inhibiting endogenous glucose production (EGP) and by stimulating glucose uptake (Rd). One of the great assets of the glucose clamp is the potential for teasing apart these two effects of insulin on glucose handling. Over three decades accurate methods were established to measure rates of endogenous glucose production—even under conditions of substantial glucose turnover that is observed during clamps [26,43–46]. These methods involve the infusion of glucose either labeled with tracer (usually 3-^{3}H-glucose), or stable isotopes such as 6,6 dideuterated glucose. Glucose output is calculated based upon the dilution by unlabeled endogenously produced glucose of the labeled glucose pool in extracellular fluid (Figure 15.3).

Great care is necessary to make accurate calculations of endogenous glucose production and glucose uptake during glucose clamps [26,45–50]. The large potential error is due to the considerable glucose turnover stimulated by hyperinsulinemia. Endogenous production is the difference between two large numbers: total rate of glucose disposal minus the rate of exogenous glucose infusion. Small errors in estimating either of these rates will cause a very large error in calculation of glucose output. Finegood and colleagues proved that to make an accurate calculation, exogenous glucose must be labeled
Figure 15.3 One-compartment model of glucose kinetics for estimation of endogenous glucose output (HGO equal to Ra) and glucose uptake (Rd). G, plasma glucose concentration (mg dL^{-1}); T, plasma tracer concentration (μCi mL^{-1}).

at a specific activity or enrichment similar to that attained when labeled moiety is infused into the fasting patient [44]. Under such conditions plasma specific activity remains near steady-state and accurate EGP is calculated. Impurities in commercial labeled glucose preparations can lead to spurious results [49]; thus tracer should be checked and purified if necessary. Also, even being unaware that so-called *50% D/W dextrose solution is only 45.4% glucose* can lead to large errors. Thus, it is important to be vigilant in these calculations and to be familiar with the literature on these subjects.

Based upon accurate methods applied to normal individuals, suppression of glucose output by liver is much more sensitive to insulin ($ED_{50} \sim 25$ mU L^{-1}) than stimulation of glucose uptake ($ED_{50} \sim 60$ mU L^{-1}) [48,50]. Reduced insulin sensitivity as assessed by the clamp method has been demonstrated in an enormous variety of physiologic and pathophysiologic situations including fasting, impaired glucose tolerance (IGT), polycystic ovarian syndrome, pregnancy, children of low birth weight, sedentary lifestyle, obesity, and acromegaly, as well as many ethnic groups from around the globe. Comparing insulin resistance in these different conditions and populations is important because insulin resistance is a primary risk factor for diabetes, but also for many other chronic diseases, including cardiovascular disease, hypertension, and cancer.

A quantitative index from the glucose clamp

As stated, glucose infusion rate during the clamp is an index of insulin sensitivity. Because insulin suppresses endogenous glucose output and increases glucose disposal, infusion of glucose must compensate for both changes under hyperinsulinemic but euglycemic conditions; the infusion rate is thus the sum of these two effects:

Glucose infusion rate = Increase in glucose disposal

+ Suppression of endogenous glucose production

Changes in either of these components on the right-hand side of this equation may be regarded as contributing to insulin sensitivity; percent suppression of EGP is often considered hepatic insulin sensitivity, whereas increase in glucose disposal (Rd: expressed as mass per unit time per unit body size) is reflective of "peripheral" insulin sensitivity (usually considered the effect of hyperinsulinemia on glucose uptake by skeletal muscle). In populations of normal subjects knowing EGP and Rd changes are often sufficient; however, in pathologic conditions they may be misleading. Glucose uptake is a nonlinear function of glucose and insulin [43,51,52]. It therefore may not be correct to compare Rd values in individuals assessed at different glucose levels or at different insulin levels [43,51]. Generally subjects with fasting hyperglycemia may have their fasting glucose values normalized by infusing exogenous insulin acutely, or overnight [53–55].

Insulin is degraded very rapidly under normal conditions. Because the liver degrades 50% or more of the insulin presented to it during a single passage of blood from the abdominal portal vein to the hepatic veins, the plasma level of insulin achieved during a euglycemic clamp can vary substantially. Generally insulin clearance is reduced in insulin-resistant situations, resulting in proportionately greater plasma insulin levels during insulin infusion during the clamp [56–58]. For example, in the canine model, simple fat feeding for 6 weeks decreased fractional insulin clearance by the liver from 60 to 40% for a single passage [59]. To compensate for differences in insulin clearance, many investigators divide glucose disposal (Rd) by the increment in insulin under steady-state conditions (M/I).

We proposed a single variable, the "insulin sensitivity index," which attempts to correct or normalize for differences in plasma glucose and insulin concentration at which clamps may be performed [60–63]. The clamp-based index is defined as the following:

$$S_{iP} = \frac{\Delta R_d}{\Delta I * G}$$

in which SiP represents peripheral insulin sensitivity, the numerator is the increase in glucose disposal during a clamp, and the denominator is the product of the insulin increment during the clamp, and the ambient glucose at which the clamp is performed. Thus, this equation calculates increase in glucose clearance per unit increase in the plasma insulin value (Figure 15.4).

Insulin action dynamics

Insulin sensitivity from the clamp is expressed in terms of the steady-state value reached after a period of hyperinsulinemia. A dose–response can be constructed and sensitivity can be expressed as the ED_{50}, that is, the concentration for half-maximal stimulation of Rd as a function of dose. Alternatively, sensitivity can be expressed (as it usually is) as the Rd at a specific dose of insulin, which may be low, intermediate, or a maximum dose. It is often assumed that steady-state rate of glucose uptake is reached by 180 min after onset of the insulin infusion. In fact, steady-state glucose uptake is not reached at
Figure 15.4　Relationship between plasma glucose concentration and whole-body glucose uptake (Rd) at two levels of insulinemia.

3 h [64,65]. Glucose uptake rate at 3 h is only 2/3 the "true" steady-state, which is not achieved until 6 h (Figure 15.5). Certainly, shorter periods (e.g. 120 min) are inadequate to reflect steady-state rates of uptake [43,63,66].

Rd at "steady-state" does not incorporate the events that account for the slow time course of activation of glucose uptake [43,63,67]. Events that may determine the time course of glucose uptake in the face of hyperinsulinemia include dynamics of plasma insulin itself [66], access of insulin to the insulin-sensitive tissues (primarily skeletal muscle, liver, and adipose tissue) [68,69], binding of insulin to receptors, and the downstream signaling pathways and mobilization of glucose transporters (primarily glucose transporter 4 (GLUT4; [70–77]). It has been of interest to examine the *in vivo* pathway of insulin action during clamps to identify the rate-limiting step which determines insulin dynamics *in vivo*. It is possible
Figure 15.5　Time course of glucose uptake (Rd) during infusion of regular insulin. Rd does not reach steady state at 3 h after the start of the insulin infusion. Source: Hamilton-Wessler 2000 [65].

that changes in access to insulin-sensitive cells could contribute to a "dynamic" insulin resistance, because insulin action does not generally reach the hyperinsulinemic steady-state value assessed during euglycemic clamp studies.

Access to sensitive cells includes the actual process of movement of insulin across the endothelial cells as well as any effect of insulin to access so-called "nutritive" capillaries (i.e., those that perfuse insulin-sensitive and glucose-utilizing or glucose-storing tissues). By measuring insulin in plasma and lymph simultaneously, we were able to determine that it was the movement of insulin between the plasma and the interstitial fluid compartment that was the determinant of insulin action dynamics [68,78].

It is clear that cellular sensitivity to the hormone is not the only action of insulin on carbohydrate metabolism which results in insulin resistance. The ability of the hormone to access sensitive tissues is reduced because of reduced transendothelial transport as well as failure to increase flow through nutritive capillaries. The relative importance of these dynamic components of insulin action under different conditions remains to be established. Given the various dynamic features that contribute to overall insulin action, it is reasonable to utilize the *dynamics* of insulin action, rather than quasi steady-state alone to represent *in vivo* insulin sensitivity. One approach that utilizes insulin action dynamics is the "minimal model" approach.

Dynamic insulin action: the minimal model

In the normal 24-h day, the insulin-sensitive tissues are never exposed to steady-state conditions. After a meal, glucose and insulin are changing, and the rate of glucose uptake lags in time behind the time courses of glucose and insulin. It may be preferable to measure insulin action from a dynamic relationship between glucose, the primary nutritive carbohydrate, insulin, the primary anabolic hormone, and the rate of glucose disposition. One approach to such a measurement is the frequently sampled intravenous glucose tolerance test (FSIGT) coupled with the "minimal model." The underlying concept behind the minimal model approach will be outlined herein, but the reader should refer to more extensive presentations for added information and detail [43,60,79–83].

Concept

As discussed, intervening to "open the loop" to perform a glucose clamp requires resources in dollars and labor. Using the power of the digital computer and modeling obviates the need to maintain constant plasma glucose and insulin to obtain a sensitivity measure. To measure dynamic sensitivity the insulin/glucose regulating system must be perturbed. While the administration of oral glucose might be considered the simplest approach given the acceptance of the OGTT as a diagnostic procedure, oral glucose has substantial limitations due to lack of control over the rate of glucose appearance in the extracellular fluid [84,85] (see later). Therefore, intravenous administration was the protocol of choice. The explicit detailed
Figure 15.6 Plasma glucose and insulin dynamics during a frequently sampled intravenous glucose tolerance test (FSIGT). Source: Unpublished data courtesy of Anne E. Sumner, MD.

dynamic relationship between glucose and insulin following intravenous glucose is measured by collecting frequent blood samples (Figure 15.6).

While many hormonal and neural signals can impact plasma dynamics, it has been shown that in the main, a few factors dominate the time course of glucose and insulin following glucose injection. These are (1) endogenous glucose production (by liver predominantly and also kidney); (2) insulin secretion and insulin clearance; (3) effect of insulin to alter the rate of glucose uptake by insulin-dependent tissues (mostly skeletal muscle) by a variety of mechanisms including transporter mobilization, enzyme activation, changes in perfusion of nutritive tissues, endothelial transport; and (4) glucose uptake by tissues independent of insulin (brain, gut, red blood cells).

The model

It was a challenge to develop a computer model that could account for plasma dynamics in a compact but accurate package. The model was the simplest representation we could devise, which was based upon known physiology, and which could accurately describe moment-by-moment plasma dynamics. The model continues to thrive in that it continues to be the basis for a large number of clinical investigations (∼50 per year) as well as a robust literature related to its mathematical and computer characteristics [43,60,61,79–82,86–96].

Practical application of the minimal model

In contrast to the glucose clamp procedure, neither online measurements nor external control of infusions are necessary to perform the minimal model procedure. Temporary intravenous lines are placed in antecubital veins in a relaxed

Table 15.1 Metabolic parameters estimated from an FSIGT by computer analysis using the MINMOD program

AIR$_{glucose}$	*First-phase insulin release*: Reflects β-cell functionality
S$_I$	*Insulin sensitivity index*: Reflects ability of insulin to enhance effect of glucose to normalize its own concentration after injection
S$_G$	*Glucose effectiveness*: Effect of glucose to enhance net glucose disappearance, at basal insulin in absence of dynamic insulin response
K$_1$	*Fractional metabolic clearance rate of insulin*: Reflects rate of clearance of injected insulin from the circulation. Related to first-pass hepatic insulin clearance
DI	*Disposition index*: Equals SI × AIR$_{glucose}$. Reflects insulin secretion *normalized to the degree of insulin resistance*

subject. After basal sampling, glucose is injected and frequent sampling is begun. To facilitate the computer's ability to estimate metabolic parameters (cf. Table 15.1) insulin is injected at 20 min and sampling continued until 3 h [92,93]. Samples are spun and plasma is stored frozen for later analysis of glucose and insulin. It is straightforward for two experimenters to perform the FSIGT on one subject.

Yields from the minimal model

By computer analysis using the program MINMOD Millennium [97], a set of values is calculated for each individual subjected to the FSIGT test (Table 15.1). Insulin sensitivity from the model is expressed as parameter S$_I$. *The latter parameter from the minimal model is fundamentally analogous to the previously mentioned S$_{IP(clamp)}$ estimated from the euglycemic clamp* [60]. In fact, the parameters are strongly correlated with each other [60–62,98–100]. The correlation is not perfect, however. This may be due to inherent errors in measurement of each (errors in plasma measurements, sampling times, etc.). Also, it may be due to the fact that the minimal model S$_I$ is estimated from a dynamic test, whereas the analogous clamp parameter is from a steady-state test [82]. It is apparent that these very different tests—the FSIGT versus the clamp—may not be measuring the exact same things, but what they are reflecting are highly correlated. The clamp emphasizes steady-state effects of insulin on glucose uptake and production often at a single insulin level. The minimal model also measures the factors that determine the rates of distribution of insulin as well as glucose among different compartments of the organism, and factors that determine how rapidly insulin can stimulate glucose metabolism by accessing tissues (whether by changing blood flow distribution or endothelial transport) and by mobilizing transporters, activating enzymes, changing expression, and so on. The relative importance of insulin resistance to pathogenesis disease, whether measured by a steady-state or a dynamic approach, is of great interest.

Additional important information is gleaned by using the minimal model approach. One important parameter, also obtained from the euglycemic clamp (by the ratio of the increment in plasma insulin to the insulin infusion rate) is an estimate of the metabolic clearance rate of the hormone. As shown in Figure 15.6, insulin is injected into the patient 20 min after the glucose. The rate of decline in the insulin level after this injection is proportional to the rate of insulin clearance. The metabolic clearance rate of insulin is estimated by the following equation:

$$MCRI(l/kg/\min) = \frac{Dose}{\int_{t=20}^{\infty} (Ins(t) - Ins(0))dt}$$

where MCRI represents the metabolic clearance rate of insulin, Dose reflects the amount of insulin injected at t = 20 min during the FSIGT (in mU kg^{-1}), Ins(t) is the plasma insulin concentration at time t, and Ins(0) is the insulin concentration at t = 0 (=basal insulin, in mU L^{-1}).

However, this estimate is imperfect, because the time course of plasma insulin is also modified based upon the change in the endogenous release of the hormone. In our laboratory, we are developing new methods for providing a more accurate estimate of insulin clearance, which utilizes the C-peptide measurements made following the insulin injection at 20 min after glucose.

The wonders of lactate

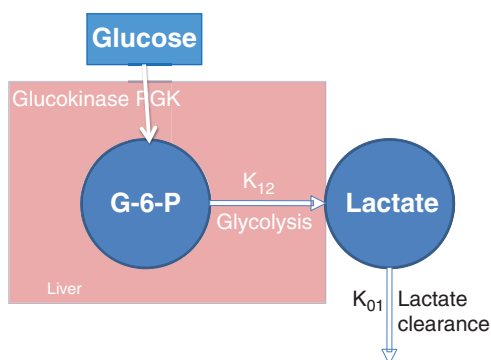
Very recently, our laboratory has made a major improvement in the use of the minimal model to assess insulin sensitivity and evaluate its importance in metabolic control. During the FSIGT, as it is practiced, there is initially a large increase in glucose concentration, due to the glucose injection, there is an endogenous finite insulin response in normal individuals, and the insulin is then increased again at 20 min after the exogenous insulin injection. We considered the question of the fate of the injected glucose before the secondary insulin injection. In the absence of a large increase in insulin, much of the glucose is disposed by an insulin-independent mechanism, a process we termed "glucose effectiveness." Tissues which can dispose of glucose independent of a large dynamic insulin response include the brain, the liver, and red blood cells. In fact, hepatic glucose uptake is independent of the dynamic insulin response [101]. We have therefore hypothesized that the major site of glucose uptake during the FSIGT is by the liver. What is the fate of the glucose in the liver during the FSIGT? Under resting conditions, little of the glucose will be anaerobically metabolized, as there is little need for additional energy. Liver glycogen synthesis under these conditions will proceed slowly [102]. Therefore it is likely that much of the glucose will proceed down the glycolytic pathway, and exit the liver as lactate. It is possible, therefore, that the plasma lactate levels during the FSIGT *reflect the ability of the liver to take up glucose in the hyperglycemic situation*. The rate of liver glucose uptake is limited by the phosphorylation of glucose in the liver—which is limited by the activity of glucokinase in the liver. We have modeled the relationship between plasma


Figure 15.7 Graphical depiction of the two-compartment model of lactate kinetics.

glucose and lactate during the FSIGT (Figure 15.7; [103]), and this model yields a parameter which represents the activity of glucokinase in the liver. We therefore can suggest that the activity of glucokinase can be estimated from the FSIGT. This activity is important because it is likely the major component of the glucose effectiveness.

There is now evidence that glucose effectiveness is under control by the CNS [104]; the latter concept has emerged from the use of the minimal model to assess liver glucose uptake. The latter studies, conducted in collaboration with M. Schwartz and his colleagues, utilize the minimal model in the rodent. In fact, we have collaborated with Alonso and O'Donnell and colleagues in their development of a minimal model procedure in the mouse [105]. Additionally, a genetic variant has been identified for the expression of glucokinase regulating protein, and it is possible in the future that the use of the minimal model accessing lactate will be used for identifying new risk variants for T2DM and other insulin-resistance syndromes.

Hyperbolic relationship between insulin sensitivity and insulin secretion: the disposition index

Diabetes, characterized by elevated blood glucose concentration, is reflective of an inability of the patient to regulate the plasma glucose concentration within normal limits. How is this regulation maintained in the normal individual?

Insulin resistance is common in Westernized societies. Yet, most insulin-resistant individuals do not have diabetes. Diabetes is prevented by the compensatory characteristics of the pancreatic β cells. Insulin sensitivity is reduced in many normal as well as pathophysiologic states. Among the normal states are pregnancy and puberty; pathologies include obesity and infection. Pathologies include not only T2DM, but hypertension, colon cancer, and polycystic ovarian syndrome.

Diabetes is prevented in many states of severe insulin resistance by the robust compensatory function of the cells of the pancreas. In fact, there is a predictable β-cell response to insulin resistance (Figure 15.8) [106]:

$$S_I \times AIR_{glucose} = DI$$
Figure 15.8 The hyperbolic insulin sensitivity/secretion curve. It is hypothesized that in the course of environmentally induced reduction in insulin sensitivity, "normal" pancreatic islets will respond by upregulation of insulin response (solid arrow pointing upwards). An improvement of insulin sensitivity would be associated with a decrease in insulin response (solid arrow pointing left). Any β-cell defect would result in a parallel hyperbola nearer the origin.

where the three variables are defined as in Table 15.1. This equation is a *rectangular hyperbola*, which predicts that for a given decrease in insulin sensitivity, there will be a proportionately equal and opposite increase in β-cell sensitivity to glucose stimulation. The disposition index defines the position of the hyperbolic curve on the sensitivity/secretion plot. If the DI is *high*, then the β cells mount a robust response to a decrease in S_I; if the DI is *low*, such a value is reflective of unresponsive β cells. Subjects at risk for T2DM have a low disposition index [89,106–109]. There is evidence that the DI value is determined by genetics as well as environment [82,110,111]. The minimal model, therefore, provides a method for assessing insulin sensitivity in the intact organism by combining a relatively straightforward experimental protocol with the power of the digital computer to model real data. Software to calculate parameters has been available for some years making the methodology available to all clinical investigators. The method continues to be used in laboratories throughout the world.

Surrogate measures of insulin sensitivity

Laboratory methods for measuring insulin action have been shown to be accurate. However, under certain conditions application of these methods is difficult if not impractical. Some studies call for assessment of insulin action in even hundreds of thousands of subjects. Of course, the glucose clamp is not amenable to larger studies. The minimal model has been used to measure insulin sensitivity and DI in studies of populations in excess of 1000 [94,110,112], but not in multiples of that number of subjects. Are there simpler but accurate methods for use in large populations? We shall focus on two classes of

"surrogate" measures of insulin sensitivity: indices based upon fasting measures, and indices based upon the OGTT.

Fasting insulin

Kahn and his colleagues have reported a curvilinear relationship between *fasting insulin* and insulin sensitivity [113], one that is similar to stimulated insulin release. In an individual with healthy β cells, because there is a defined relationship between secretion and insulin sensitivity, it could be argued that measuring one is as good as measuring the other. Thus, if insulin sensitivity is low, fasting insulin will be elevated, and vice versa. Therefore in a group of subjects with similar β-cell *function* we may expect elevated insulin to reflect insulin resistance. Similarly, with healthy β cells, insulin resistance will be reflected in elevated fasting insulin, as well as elevated β-cell secretory response to stimuli such as glucose, arginine, GLP-1, or other secretagogues. It is arguably appropriate to utilize fasting insulin or a provocative index of β-cell function as a surrogate with the following caveat: *fasting insulin per se, or other indices based upon the fasted state, should be considered accurate surrogates for insulin sensitivity* **only** *when comparing between or among individuals with equivalent functional activity of the pancreatic β cells* [114].

The downside associated with using fasting insulin (or other related indices of insulin secretion) becomes clear if we consider comparing among groups or individuals with differing islet secretory function. Let us consider as an example comparison of fasting insulin between normal individuals and individuals with IGT. The latter group is not only insulin resistant, but is characterized by a β-cell defect of at least 50% [115–117].

Comparing the normal subjects with insulin-resistant subjects with IGT, plasma insulin concentration, or insulin response to glucose could be identical. Thus, the fasting insulin concentration will not represent an accurate reflection of insulin sensitivity comparing individuals or groups for whom cell function is not identical. In practice, individuals with similar β-cell function are not often compared; it is more usual to compare normal subjects with those at risk for disease (e.g. IGT [115–117], gestational diabetes after term [87,107], first-degree relatives of type 2 diabetic patients [118,119]).

The previous discussion demonstrates that *fasting insulin per se cannot be considered an accurate surrogate for insulin sensitivity (or resistance) under most conditions*. Nevertheless, there is a substantial literature using the fasting insulin value for just this purpose [120–122]. At the very least, the careful observer must consider with care reports of fasting insulin as a surrogate for insulin resistance. If there is even a latent subtle β-cell defect in a group of subjects, any reported value of fasting insulin will likely underestimate the degree of insulin resistance.

Other surrogate measures

Besides fasting insulin itself, there are various other surrogate measures based upon fasting values alone, which have been exploited in population studies. The first to appear in the literature was the index proposed by Dr. Peter Bennett. Others include the homeostasis model assessment index insulin resistance measure (HOMA), and the "QUICKI" [123–136]. Note that these indices are indeed similar; they represent insulin resistance as proportional to either the product or the inverse of the product of fasting insulin and fasting glucose. In fact, in nondiabetic subjects plasma glucose differs little compared to large variance in fasting plasma insulin. Therefore, in nondiabetic subjects, both HOMA index and Bennett's index are approximately proportional to the fasting insulin concentration. As discussed, similar to fasting insulin, these indices will not reflect insulin sensitivity accurately in nondiabetic subjects with differing β-cell function.

Quon and colleagues introduced the "QUICKI" index [125]. Quon et al. equate insulin resistance to the inverse of the sum of the logarithms of fasting plasma glucose and fasting plasma insulin. The value of insulin resistance emerging from this index will depend upon the units of glucose and insulin, and the relative importance of these components will depend upon whether they are expressed in European (SI) units (mM glucose and pM insulin) or in units used in the United States (mg dL^{-1} glucose and µU mL^{-1}). Also, despite the logarithmic transformation, QUICKI values exhibit nonlinear proportionality to fasting plasma insulin and will, like fasting insulin, underestimate insulin resistance in a population with a latent decrease in β-cell function. In fact, QUICKI and HOMA are formally identical to each other, as evidenced in the measures made in a large number of individuals (Figure 15.9).

The HOMA index of insulin resistance is extremely simple to calculate ((fasting glucose × fasting insulin) / 22.5). Therefore it has been used in a very large number of publications. However, it must be used with great caution. Because the fasting insulin is dependent not only upon insulin *sensitivity*, but also on insulin secretory function as well as metabolic clearance of insulin, the HOMA is a mixed index dependent upon all these physiologic parameters, and is not a direct measure of insulin sensitivity. The limitations of this measure have recently been documented in a series of studies [137,138]. Xiang and colleagues have shown that HOMA does not detect longitudinal changes in insulin resistance in a population at risk for diabetes [137]. It fails to detect insulin resistance associated with surgical trauma [138]. In a very recent study from our group done by Ader et al. [114], we examined whether HOMA could detect insulin resistance associated with a fat diet in the canine model. We measured insulin sensitivity with the euglycemic clamp, with the minimal model, and with HOMA. While the clamp and FSIGT values were strongly correlated, there was no significant correlation between the HOMA index and insulin sensitivity measured by either clamp or FSIGT. More significant, there was a correlation between HOMA and insulin response (Figure 15.10). Therefore based upon this study, HOMA results must be treated with a degree of skepticism, regarding insulin sensitivity per se.
Figure 15.9 Comparison of HOMA and QUICKI in normal children. Note that a mathematical conversion (log HOMA vs. 1/QUICKI) results in a 1:1 relationship between these variables. Thus, they are essentially identical measures, differing only by an algebraic manipulation.
Figure 15.10 Correlation of HOMA estimate of insulin resistance with glucose-stimulated insulin response. Source: Ader (Epub ahead of print) [114].

Thus, indices based upon fasting measurements of insulin alone or fasting insulin plus fasting glucose should not be considered accurate indices of insulin resistance comparing groups with possible inequalities in β-cell health. Because we are often comparing between individuals or groups with differing islet function, it must be concluded that fasting insulin, as well as other surrogate measures based upon fasting values alone, may not be accurate. Certainly they are inaccurate compared to measures available from laboratory procedures such as the euglycemic clamp or the minimal model.

Insulin sensitivity based upon the OGTT

The previous discussion suggests that "quick and dirty" indices from fasting values may not be accurate, and it is often true that laboratory procedures are impractical. Recently, it has been suggested that indices calculated from the OGTT may be useful for population studies. For decades the OGTT has been used as a screening test and a diagnostic tool for diabetes and IGT [139,140]. It might be ideal if one could classify the state of

carbohydrate tolerance and simultaneously measure insulin sensitivity and β-cell function. As long ago as 1981, Voors et al. suggested the mathematical product of the 1-h glucose and the 1-h insulin concentration as "peripheral insulin resistance" [141]. Ten years later, Cederholm and Wibell expressed sensitivity as the ratio of the glucose metabolic clearance rate to the logarithmic transformed mean serum insulin concentration [141]. This latter index was later modified by Gutt et al. and shown to correlate with insulin sensitivity values derived from the euglycemic clamp [142]. More recently, Matsuda and DeFronzo applied a square root conversion of the products of fasting OGTT glucose and insulin to correct for the nonlinearity of the values [143]. Stumvoll et al. performed multiple regression of several demographic parameters (body mass index, sex, waist to hip ratio, OGTT glucose and insulin) upon sensitivity from the euglycemic hyperinsulinemic clamp test [144]. Thus, their approach included as independent variables metabolic characteristics which themselves can alter insulin action [145–148].

The OGTT-derived estimates of insulin sensitivity mentioned earlier correlated with insulin sensitivity values obtained by the euglycemic clamp technique (Table 15.2). Several of the indices were additionally tested in different ethnic groups [149–151]. Kanauchi et al. showed that Matsuda's ($r = 0.45$), Gutt's ($r = 0.64$), and Stumvoll's ($r = 0.53$) formulas correlated modestly in a Japanese population with insulin sensitivity data from euglycemic clamps [151]. Kuo et al. reported the Matsuda index and the homeostatic model assessment equally applicable for estimation of insulin sensitivity in Chinese diabetic patients and their offspring [150]. In contrast, Chiu et al. [149] reported that the estimated indices (Matsuda and Stumvoll) correlate with clamp-derived insulin sensitivity in a wide spectrum of glucose-tolerant healthy subjects, but that they are less likely to detect differences in insulin sensitivity among different ethnic groups (Asian Americans, African Americans, Caucasian Americans, and Mexican Americans). However, the estimations of insulin sensitivity and β-cell function by OGTT-derived methods failed to reproduce the hyperbolic relation [152], which is well established for the relation between β-cell function

Table 15.2 OGTT-derived and fasting indices of insulin sensitivity are correlated with clamp-derived estimations of insulin sensitivity.

Insulin sensitivity indices	Equation	n*	r	Reference
$ISI_{0,\,120}$ index	$\dfrac{75000\,\text{mg} - (Gk_0 - Gk_{120}) \times 0.19 \times BW}{120 \times Glc_{mean} \times \log\left[Ins_{mean}\right]}$	135	0.63	[142]
Stumvoll index	$0.226 - (0.0032 \times BMI) - (0.0000645 \times Ins_{120})$ $- (0.0037 \times Glc_{mean})$	104	0.79	[144]
Matsuda index	$\dfrac{10000}{SQRT\left(Ins_0 \times Glc_0\right) \times \left(Ins_{mean} \times Glc_{mean}\right)}$	153	0.73	[143]
HOMA-IR	$\dfrac{\left(Ins \times Glc\right)}{22.5}$	115	−0.82	[136]
QUICKI	$\dfrac{1}{\left(\log\left[Ins\right] + \log\left[Glc\right]\right)}$	56	0.78	[135]

*n = number of subjects in respective study.

and insulin sensitivity when measured by more established methods [106].

It is clear that a correlation between proposed OGTT-derived indices and clamp-derived insulin sensitivity may exist. However, the OGTT-derived indices contain endogenous insulin response as an important term in their calculation and it cannot be excluded that reported correlations reflect islet cell response rather than insulin sensitivity per se. If it is true that OGTT-based methods reflect secretion rather than sensitivity, application of the OGTT methods to subjects with impaired β-cell secretory capacity (e.g. those with impaired glucose tolerance, gestational diabetes, T2DM) may underestimate insulin resistance, as postload hyperinsulinemia would be reduced and they may not be accurate for diabetic patients. Confirming this latter weakness, correlations between OGTT-based indices and clamp-based sensitivity [143,153] were lower when the indices are employed in subjects with T2DM.

Poor reproducibility of the 75 g OGTT also limits the value of the OGTT [154]. The overall test-to-test reproducibility (coefficient of variation) of the OGTT is no more than 65% [155]. The inherent variability is likely due to high day-to-day variability in gastrointestinal function (gastric emptying, absorption, incretin effect). It is well established that a delay in gastric emptying or reduced glucose absorption will result in lower glucose excursions as well as lower insulin levels [84,156,157]. In fact it has been demonstrated that gastric emptying alone accounts for 35% of the variance in peak plasma glucose after a 75 g OGTT in both healthy volunteers and patients with T2DM [84].

We have investigated the possible effects of variability in islet cell function as well as variability in intestinal glucose absorption on glucose and insulin patterns and OGTT-based indices using a computer model [158]. The glucose and insulin time series simulated for a normal healthy subject closely match published data [159]. The OGTT data simulated under these conditions indicate that ±50% changes in β-cell sensitivity or glucose absorption have a far greater impact on the pattern of glucose and insulin than alterations of insulin sensitivity itself. An imposed 50% reduction of insulin sensitivity caused only very minor changes in sensitivity calculated by those indices (Table 15.3). In contrast, isolated alterations of β-cell sensitivity and glucose absorption resulted in considerably higher or lower apparent values of insulin sensitivity from

Table 15.3 OGTT-derived and fasting indices were calculated from the model-predicted glucose and insulin concentrations.

	Normal values	Imposed changes in metabolic variables					
		Δ Insulin sensitivity		Δ β-cell sensitivity		Δ Glucose absorption	
		+50%	−50%	+50%	−50%	+50%	−50%
		Relative change in insulin sensitivity values					
$ISI_{0,\,120}$ index	83.2	8	−14	−5	10	−21	34
Stumvoll index	0.11	2	−6	−3	1	−9	9
Matsuda index	4.0	10	−14	−26	69	−21	37
HOMA-IR	1.64	−8	10	36	−44	0	0
QUICKI	0.36	2	−2	−5	10	0	0

Note: Relative changes of the individual sensitivity values under assumption of isolated 50% changes of insulin sensitivity, insulin secretion, and glucose absorption are shown in this table.

almost all indices. While these results are from a simulation study, they suggest strongly that one must be very careful in interpreting differences in OGTT values in terms of insulin sensitivity per se because differences in metabolic parameters other than insulin sensitivity may have greater effects on OGTT. Therefore alterations in OGTT cannot be readily interpreted to reflect changes in insulin sensitivity alone, but may reflect changes in gastric emptying, insulin secretion, glucose effectiveness, and so on. Clearly, however, the OGTT (or meal tolerance tests) are far superior for assessment of insulin sensitivity than measures based upon fasting glucose and insulin alone.

Conclusions

The objective to accurately measure insulin sensitivity (i.e., "insulin resistance") in patients remains an important goal. Insulin resistance is a risk factor for a plethora of chronic diseases (diabetes, cardiovascular disease, hypertension, colon cancer). Extensive efforts are under way to find genetic variants underlying insulin resistance. To study these diseases, and to intervene early in their pathogenesis, requires that we quantify insulin resistance as one important risk factor. To measure sensitivity accurately it is best to use a method that observes in some fashion the metabolic effect of insulin given intravenously. Thus, the glucose clamp and the minimal model are accurate and reproducible methods. While one must remain vigilant regarding limitations of these methods, they may be applied with confidence under a wide variety of conditions.

Unfortunately it is not possible to be equally sanguine in recommending simpler (i.e., surrogate) methods. While it may be appropriate to use fasting insulin to reflect insulin resistance in patients without any degree of β-cell failure, it is usually not possible to determine a priori whether any such defect exists. Thus, one can report fasting insulin simply as a qualitative reflection of insulin resistance. Indices that also include glucose appear to add little to the fasting insulin itself. There is strong evidence that the HOMA index does not measure insulin resistance accurately, and in fact may be a better index of β-cell response. Because the purpose of using surrogate methods is to differentiate these two physiologic functions—insulin sensitivity versus β-cell response—it is not possible to recommend the use of surrogate methods based upon fasting values, or at least be highly sensitive to the limitations of using them. Thus, if a genetic variant related to HOMA (or its logarithmic cousin, QUICKI) is identified, one cannot say with confidence the phenotypic trait related to the measured value. Caution in interpretation is the watchword.

Insulin sensitivity measures based upon oral glucose or meals are superior to fasting measure-based surrogates. One must be cognizant, however, of the possible involvement of alterations in nutrient absorption as well as gastrointestinal hormones in the values which emerge. Hormones such as GLP-1 alter insulin action [160], and such effects will alter the sensitivity measures emanating from the oral tests.

Clearly more work is justified to identify new and novel methods to obtain accurate and precise measures of insulin action *in vivo* from simple-to-perform tests. Among others, we continue this quest in our own Institute.

Key points

- Insulin is the most powerful protein anabolic hormone over the short term. In physiologic conditions, the anabolic effect of insulin on protein metabolism occurs during feeding, when insulin secretion promotes dietary amino acid storage in sensitive tissues, mainly skeletal muscle.

- The mechanisms by which insulin stimulates protein anabolism are complex and involve both an increase in protein synthesis and a decrease in proteolysis. These mechanisms are triggered by insulin binding to its receptor and are mediated by Akt and mTORC1 signaling.

- Insulin stimulation of protein synthesis is dependent upon amino acid availability and the hormone's ability to enhance endothelial-dependent vasodilation. In fact, endothelial dysfunction and/or a reduction in nutrient (amino acid) availability induce resistance to the stimulatory effect of insulin on protein synthesis (anabolic resistance).

- Insulin exerts differential protein anabolic effects on its target tissues. In skeletal muscle, insulin enhances protein synthesis unless amino acid availability decreases or blood flow does not increase, in which case a reduction in proteolysis prevails. In the splanchnic region, insulin influences the synthesis of some export liver proteins. It stimulates albumin synthesis both in healthy and diabetic individuals, and reduces acute phase protein synthesis in insulin deprived type 1 diabetes patients. Insulin also reduces skin protein breakdown and overall skin protein turnover with no effect on the net protein balance in healthy subjects, while it stimulates wound protein anabolism by reducing protein breakdown. At the whole body level insulin reduces protein breakdown despite its stimulatory effect on muscle and liver proteins. This apparent discrepancy may be explained by methodological limitations of the model for measurement of whole body protein turnover and/or by the possibility that insulin may also decrease the synthesis of other unmeasured proteins, offsetting the stimulatory effect on muscle protein synthesis.

- The effect of insulin on protein metabolism changes according to the pathophysiologic setting. In some conditions the stimulatory effect on protein synthesis is reduced (e.g. aging), while in others the antiproteolitic effect is enhanced (e.g. exercise) or reduced (e.g. type 2 diabetes).

Introduction

Over the last two decades it has become clear that insulin, the well-known regulator of glucose and fat metabolism, plays also a critical role in the regulation of protein metabolism. Specifically, insulin is the most powerful protein anabolic hormone over the short term. The anabolic effect of insulin on protein metabolism occurs during feeding, when the large insulin secretory bursts promote storage of dietary amino acids. It is important to underscore that, unlike glycogen for glucose and triglycerides for fatty acids, there is no inactive storage moiety for amino acids, which must be incorporated into functional proteins. Skeletal muscle contractile proteins are the largest functioning storage system for essential amino acids [1]; consequently they are a major target of the protein anabolic effect of insulin. An adequate basal insulin concentration as well as normal insulin signaling is also required to prevent rapid protein loss. Conditions of insulin deficiency (untreated type 1 diabetes), or severe insulin resistance (e.g. critical illness) are characterized by the release of large amounts of amino acids from skeletal muscle, which leads to rapid muscle wasting. Recent observational studies have also highlighted that type 2 diabetes accelerates sarcopenia, the loss of skeletal muscle mass and function with aging. These clinical observations highlight the importance of insulin for skeletal muscle homeostasis and function. However, other proteins and tissues are also significantly impacted by the protein anabolic effect of insulin, particularly in the liver and skin.

The mechanisms by which insulin regulates protein metabolism are not completely understood. While insulin action has been extensively examined *in vitro*, in cell systems, and in animal models, it is very difficult to determine if those mechanisms are also involved in the physiologic regulation of protein metabolism *in vivo*, in humans. The main reason is the complexity of the system. Insulin can potentially affect a wide variety of proteins in a variable manner. The situation is further complicated by the physiologic setting in which insulin

is normally secreted: the prandial state. During feeding, the increase in insulin concentration occurs concomitantly with major changes in substrate availability. It is thus very difficult to isolate the direct effects of insulin on protein turnover from those due to changes in amino acid and energy availability. Moreover, changes in insulin concentration also induce changes in tissue blood flow, which can significantly affect the hormone's action on protein synthesis and breakdown. This chapter will provide an overview of the known mechanisms of insulin action on protein metabolism in humans utilizing an integrative approach.

Integrative physiology of insulin action on protein metabolism

Insulin impacts a variety of physiologic functions that are regulated through the activity of an intricate array of cellular mechanisms. These mechanisms are extremely important for insulin to regulate protein turnover in metabolically active tissues, particularly skeletal muscle and the liver. In addition, insulin also triggers a series of equally important cellular events in the endothelium that allow it to exit the circulation and exert its actions on the target tissues.

This section focuses on the mechanisms that regulate the physiologic responses of protein metabolism to insulin in humans. We will follow the fate of insulin starting with its exit from the circulation to reach the target tissues, and discussing the role of insulin-induced vasodilation on protein anabolism. We will then examine the direct insulin effects on target tissues and conclude with the overall effects of insulin at the whole body level. Figure 16.1 provides a simplified depiction of the effects of insulin on the endothelium and the muscle tissue, which is the major target of insulin action on protein metabolism.

Insulin transport from the circulation to the target tissues

To exert its physiologic actions on the target tissues, insulin must first leave the circulation by crossing the endothelial barrier. This process involves changes in local blood flow (i.e., microvascular blood flow) and the ability for insulin to exit the circulation, enter the interstitial space, and bind to the target tissues' receptors. This series of events is critical for skeletal muscle to mount a protein anabolic response to hyperinsulinemia.

Extensive work from Barrett and colleagues has highlighted that a major rate-limiting step for insulin to exert its physiologic actions on skeletal muscle is its transport from the circulation to the interstitial space [2]. The model proposed suggests the existence of a saturable transendothelial transport mechanism [2,3]. Two insulin-dependent processes work in concert to regulate insulin transport: (1) the binding of insulin to its receptor and the subsequent internalization of this complex into the endothelial cell [3], and (2) the stimulation of insulin signaling in the endothelial cell [2]. More specifically,

insulin-dependent activation of the phosphoinositide 3-kinase (PI3K)-Akt and mitogen activated protein kinase (MAPK) pathways appear to have an important role in promoting insulin uptake and vesicular intracellular trafficking of insulin bound to its receptor [3]. In other words, insulin appears to stimulate its own transport across the endothelium in a positive feedback manner that requires an intact insulin signaling cascade [2]. In addition, several other proteins, including Caveolin-1 [4], appear to have an important role in supporting insulin uptake into the endothelium and the subsequent transendothelial vesicle trafficking of insulin through the endothelial cell into the interstitial space. These complex mechanisms involved in the regulation of insulin transport from the circulation to the extracellular space are a major rate-limiting step for insulin to exert its physiologic actions on the target tissues, particularly skeletal muscle [3].

Insulin-induced vasodilation

Insulin transport through the endothelium triggers a powerful vasodilatory response, which increases microvascular nutritive flow to the target tissues. The mechanism involves activation of the endothelial nitric oxide synthase (eNOS) via protein kinase B (PKB or Akt) dependent phosphorylation [5]. In turn, activation of eNOS stimulates the release of nitric oxide (NO) in the endothelial cells causing dilation of the peripheral vasculature [6].

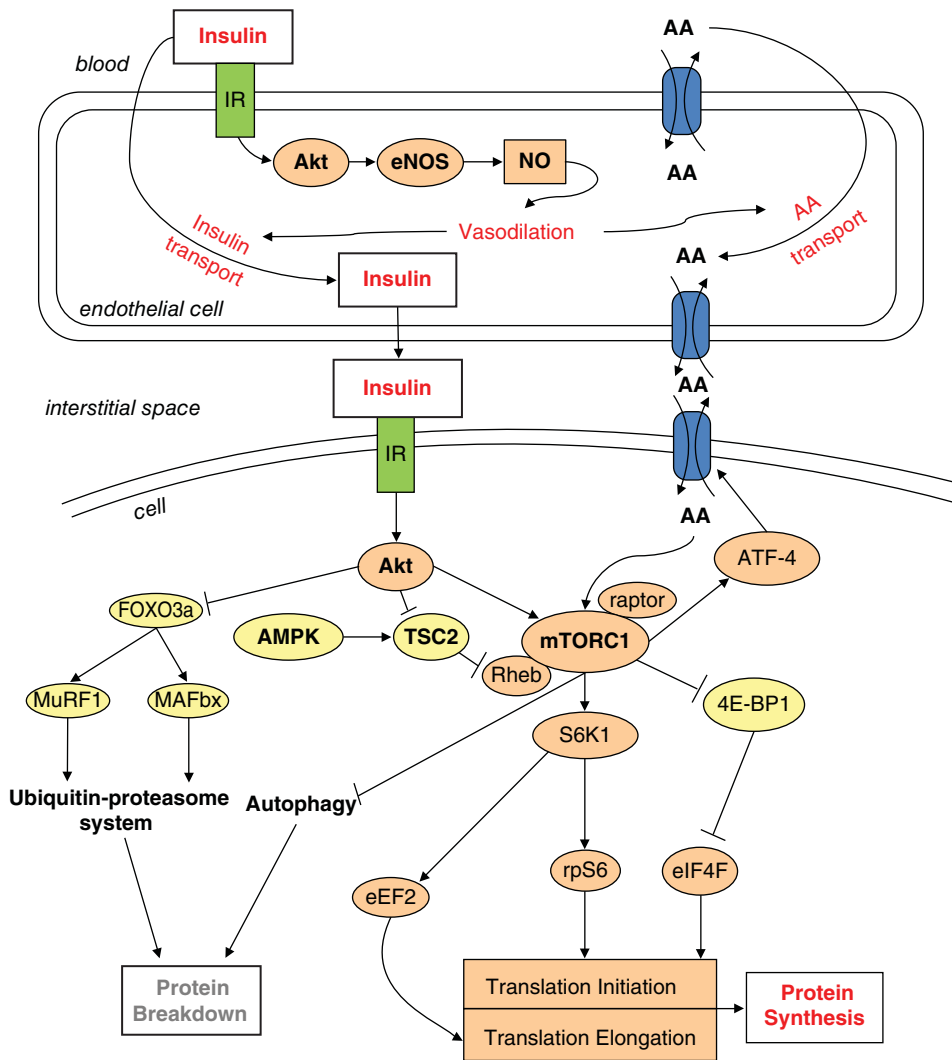
A major role for insulin-induced vasodilation in the protein anabolic response to the hormone was initially hypothesized to account for otherwise unexplainable differences in the results of earlier human studies examining the metabolic mechanisms by which insulin stimulates skeletal muscle protein growth [7]. Recent mechanistic studies in humans have demonstrated a causal relationship between the vasodilatory action of insulin and its anabolic effect on skeletal muscle protein anabolism. These experiments involved the local insulin infusion technique with euglycemic clamp to isolate the direct effect of insulin from that of amino acid and glucose availability, as well as NO synthase inhibition with NG-monomethyl-L-arginine (L-NMMA) [8]. When insulin was infused alone it increased skeletal muscle protein synthesis and net balance. However, co-infusion of L-NMMA with insulin blocked not only the insulin-induced endothelial dependent vasodilation but also the insulin-stimulated increase in skeletal muscle protein anabolism [8]. Conversely, in a condition of protein anabolic resistance to insulin that is accompanied by endothelial dysfunction, sarcopenia of aging [9], the stimulatory effect of insulin on muscle protein anabolism can be restored by normalizing vasodilation via co-infusion of insulin with sodium nitroprusside, a NO donor [9,10]. These data demonstrate that increases in blood flow and microvascular perfusion are critical for insulin to exert its anabolic effects on skeletal muscle protein metabolism. As we will discuss more in detail later, insulin's inability to trigger these endothelial events and increase microvascular flow to skeletal muscle, as observed in


Figure 16.1 Mechanisms of insulin action on protein metabolism. Insulin first binds its receptor (IR) in the vascular pole of the endothelial cell and activates Akt signaling. The insulin-IR complex is then internalized in microvesicles and transported to the interstitial pole of the endothelial cell where insulin is released into the interstitial space and can bind to its receptor on the target tissue. Increased Akt phosphorylation in the endothelial cell also stimulates the production of nitric oxide (NO) by eNOS with consequent vasodilation. Vasodilation increases the amount of tissue exposed to insulin and amino acids (AA), as well as the amino acid flux to the tissue. Blood amino acids are actively transported through the endothelial cell into the interstitial space and, eventually, to the target tissue by their specific transporters. Once insulin binds the target tissue IR it stimulates Akt, which activates mTORC1 signaling with consequent increase in translation initiation and protein synthesis. When mTORC1 is activated it also increases amino acid transporter expression via ATF-4, thus providing a positive feedback for enhanced amino acid uptake. Moreover, mTORC1 activation can reduce autophagy, decreasing protein breakdown. Another pathway by which insulin reduces protein breakdown is via Akt inhibition of FOXO3a, which reduces ubiquitin-proteasome proteolysis.

aging and other conditions of insulin resistance, significantly impairs the anabolic actions of insulin on skeletal muscle, and, in particular, insulin's ability to stimulate skeletal muscle protein synthesis [8–10].

Molecular mechanisms of insulin action on protein metabolism

After its transport out of circulation, insulin binds to the receptor in the target tissues. The metabolic actions of insulin on the target tissues are produced through insulin-dependent activation of key intracellular signaling pathways. The pathway involved in

the stimulation of muscle protein anabolism is intricately connected with the signaling pathway involved in glucose uptake. Thus, we will describe later the cellular mechanisms by which insulin regulates these two very well-defined physiologic processes. We will focus on the effects of insulin on skeletal muscle, which is the tissue most studied in humans.

Insulin increases glucose uptake in skeletal muscle through the glucose transporter type 4 (GLUT4). This process requires the translocation of GLUT4 from its intracellular storage site to the cell surface. The initial event signaling GLUT4 translocation is the binding of insulin to its cell surface tyrosine kinase receptor.

This binding triggers the phosphorylation of insulin receptor substrate 1 (IRS-1) and the subsequent phosphorylation and activation of PI3K. Activation of PI3K eventually triggers the phosphorylation of Akt (also known as protein kinase B [PKB]), which is phosphorylated by both phosphoinositide-dependent kinase 1 (PDK1) and the mammalian target of rapamycin complex 2 (mTORC2) [11]. The phosphorylation of Akt represents a critical step in insulin signaling, and is a branching point for signaling related to insulin-stimulated protein anabolism.

One of the primary downstream targets for Akt in the cellular regulation of insulin-stimulated glucose uptake appears to be the Akt substrate of 160 kDA (AS160) [12]. AS160 seems to play a role in retaining GLUT4 to its intracellular vesicles through its interaction with specific GTPases [11]. Phosphorylation of AS160 by Akt is thought to release the inhibitory effects of AS160 on GLUT4 translocation, thus allowing GLUT4 to translocate to the cell surface with support of other regulatory proteins [11]. Upon removal of the insulin signal, a majority of the GLUT4 relocates to the intracellular vesicles. In fact, in the absence of a significant insulin signal (i.e., in the fasting state) it is estimated that greater than 95% of the GLUT4 may be localized intracellularly, while only a small fraction is found on the cell surface [13]. The inability of insulin to trigger the translocation of GLUT4 to the surface of skeletal muscle cells (and adipose tissue) represents a key component in the development of insulin resistance.

The other major pathway that branches off downstream of Akt is the mTORC1 signaling pathway, which is involved in the regulation of muscle protein synthesis and anabolism. Originally, it was thought that Akt could signal to mTORC1 by phosphorylating and inhibiting TSC2, which is a direct upstream negative regulator of mTORC1. However, more recent data suggest that Akt increases mTORC1 activity by phosphorylating proline-rich-Akt/PKB substrate 40Kda (PRAS40) [14], which binds to mTOR and is a negative regulator of mTORC1 activity. The Akt-dependent phosphorylation of PRAS40 facilitates the release of PRAS40 from mTOR (perhaps via 14-3-3 binding to PRAS40) [14], resulting in increased mTORC1 activity.

Protein anabolism is largely regulated by the mTORC1 signaling pathway in humans [15,16]. It is very well understood that an activation of mTORC1 signaling triggers an increase in protein synthesis and also attenuates muscle protein breakdown, although the latter mechanism is less well characterized in humans. Collectively, the increase in protein synthesis and the decrease in protein breakdown following the activation of mTORC1 signaling creates a cellular environment that favors a positive net protein balance. In humans, these effects of insulin have been described in skeletal muscle [8–10]. The mTORC1 signaling pathway is an anabolic hub for a variety of other anabolic stimuli which interact with insulin to enhance muscle growth. These include nutrients, primarily amino acids, and contraction. The remainder of this section will focus on the cellular mechanisms through which insulin stimulates protein metabolism and activates mTORC1 signaling.

The two best-characterized downstream targets of mTORC1 are the eukaryotic initiation factor 4E binding protein 1 (4E-BP1) and p70 ribosomal S6 kinase 1 (S6K1). Phosphorylation of 4E-BP1 by mTORC1 induces the release of eIF4E from 4E-BP1 and the subsequent formation of the eIF4F translation initiation complex [17]. Phosphorylation of S6K1 by mTORC1 further enhances translation initiation, primarily that of terminal oligopyrimidine (TOP) mRNAs [18]. Activation of S6K1 also contributes to increased translation elongation via the phosphorylation of the eukaryotic elongation factor 2 (eEF2) kinase and the subsequent activation of eEF2 [17]. In addition to the role of S6K1 in mediating translation initiation and elongation, phosphorylation of S6K1 negatively regulates insulin signaling. In particular, activation of S6K1 triggers the phosphorylation of IRS-1 at specific amino acid residues, which inhibits IRS-1 and promotes insulin resistance [19]. The existence of this negative feedback loop suggests that chronic activation of mTORC1 signaling, perhaps through excess food intake, may be a mechanism that contributes to the development of insulin resistance [20].

Activation of the insulin signaling cascade also reduces protein breakdown by stabilizing lysosomes and reducing the activity of the ubiquitin-proteasome pathway [21]. In muscle, the effects of insulin on protein breakdown are in part mediated through the activation of Akt and subsequent phosphorylation of the Forkhead Box O (FOXO) 3 transcription factor. Specifically, FOXO3 is responsible for the transcription of two well-known E3 ubiquitin ligases, MuRF1 and atrogin-1, and the phosphorylation of FOXO3 by Akt inhibits the movement of FOXO3 into the nucleus [22]. Consequently, FOXO3 cannot stimulate the transcription of MuRF1 and Atrogin-1 and the ubiquitin proteasome system is attenuated. In addition, recent data indicate that FOXO3 may also mediate the transcription of genes involved in autophagy, including LC3 and Bnip [23]. Thus, phosphorylation of FOXO3 by insulin through the activation of Akt may also attenuate muscle protein breakdown via the inhibition of autophagy. Furthermore, activation of mTORC1 by insulin has also been linked to the inhibition of the autophagy system. In particular, mTORC1 phosphorylates and inactivates the ULK1 complex, which inhibits the initiation step of autophagosome formation and subsequent breakdown of proteins by autophagy [24]. Collectively, these findings highlight that there is an intricate network of cellular regulatory pathways that, when stimulated by insulin, can increase initiation of translation and protein synthesis, and also reduce protein breakdown through the inhibition of the two major proteolytic systems.

Effect of insulin on tissue amino acid availability

Control of tissue amino acid availability is an additional mechanism that appears to be necessary for activation of protein anabolism by insulin. This is particularly important in skeletal muscle. Under physiologic conditions, insulin exerts two main effects on amino acid availability.

First, insulin enhances amino acid delivery to the muscle via stimulation of vasodilation (see earlier section "Insulin-induced vasodilation"). An increase in blood insulin concentration increases the amount of tissue that is exposed to amino acids via endothelium-dependent vasodilation. In turn, the stimulation of muscle perfusion increases the flux of amino acids delivered to the tissue (i.e., the product of blood amino acid concentration by blood flow to the tissue) [8,25,26]. The increase in amino acid delivery can occur even in conditions of low blood amino acid concentrations, such as during insulin infusion in the fasting state, as long as the blood amino acid concentrations do not decrease below the lower normal value [7]. However, it is also important to underscore that vasodilation alone, in the absence of hyperinsulinemia, is unable to stimulate mTORC1 signaling and muscle protein synthesis [27]. In other words, vasodilation and increased amino acid delivery are necessary but not sufficient mechanisms for insulin to stimulate protein synthesis and anabolism. This indicates that insulin signaling must also be activated in the target tissue to stimulate protein anabolism.

Second, insulin stimulates amino acid uptake and transport into a variety of tissues including skeletal muscle [7], and is directly involved in the regulation of amino acid transporter mRNA and protein expression [28]. This process is emerging as a major regulator of skeletal muscle protein homeostasis [29]. Specifically, activation of PI3K by insulin stimulates downstream activation of Akt, which, in turn, activates mTORC1 [14]. Once activated, mTORC1 not only stimulates protein synthesis via S6K1 [18], but also increases the expression of amino acid transporters via ATF4 in cell systems [28]. Thus, an impaired Akt/mTORC1 signaling can decrease amino acid transport into the muscle cell and blunt muscle protein synthesis. Kinetic studies using stable isotope methodologies have highlighted that hyperinsulinemia does indeed increase amino acid uptake from blood into skeletal muscle in healthy young humans, and that this process appears to be a limiting factor for the stimulatory effect of insulin on muscle protein synthesis [7].

Effects of insulin on protein metabolism in specific tissues

The effects of insulin on protein metabolism vary in the different tissues and organs. In some tissues, insulin exerts its anabolic action primarily via increased protein synthesis, while in others its antiproteolytic effect prevails. We will discuss below the effects that insulin exerts on the tissues that contribute the most to protein metabolism at the whole body level: skeletal muscle, splanchnic tissues, and skin.

Skeletal muscle

Skeletal muscle contains approximately 50% of the body protein [1]. Insulin is an important anabolic hormone in humans because it physiologically increases net accretion of skeletal muscle proteins in healthy, young adults [7,30,31].

The net anabolic effect of insulin on skeletal muscle proteins has been unequivocally reported in the literature [7,30–41]. However, the mechanisms by which insulin enhances muscle protein anabolism in humans have been the matter of intense discussion for more than two decades. Some of the studies reported a stimulatory effect of insulin on muscle protein synthesis [7,31,32,37,41,42], while others reported primarily a decrease in muscle protein breakdown [7,30,33–36,40,41]. There are several possible explanations for these discrepancies between human studies.

First, methodological issues should be considered. Muscle protein turnover is typically measured on the leg or the forearm with stable isotope tracer methodologies using the arteriovenous balance technique and/or the precursor-product method [43]. Selection of the sampling site, leg or forearm, is critical for the arteriovenous balance technique. This method implies the measurement of the balance of unlabeled amino acids and amino acid tracers across the selected limb, assuming that amino acid metabolism occurs mostly in the limb skeletal muscle. However, it is possible that the relative contribution of non-muscle tissues (skin, bone, bone marrow) to leg or forearm amino acid turnover is not the same. Insulin decreases skin protein turnover [44] (see later section on "Skin"). Bone marrow proteins are likely to turnover faster than muscle proteins because of the high cellular turnover, but no data are available on the effects of insulin on this tissue. Thus, the sampling site may have been partly responsible for some of the differences reported between studies. Selection of the arteriovenous balance model to calculate muscle protein turnover is even more important and can significantly affect the conclusions of the study. There are three fundamental models available to measure human muscle protein synthesis [43]: the two arteriovenous balance models, two-pool and three-pool, and the precursor-product model. The two-pool model estimates muscle protein synthesis and breakdown using the amino acid enrichments and concentrations in the artery and vein of the selected limb. These parameters are based on the extraction of the labeled amino acid from the artery, the appearance of unlabeled amino acid from the muscle into the vein, and the net arteriovenous amino acid difference [43]. Thus, this model provides data regarding the kinetics of blood amino acids across the leg or forearm, but cannot measure the intracellular recycling of those amino acids that are released from protein breakdown and re-incorporated into proteins without appearing in the blood. In other words, the two-pool arteriovenous method allows for the measurement of the effect of treatments on the net kinetics of *blood* amino acids across the selected limb, while not offering any insight into the actual intracellular amino acid kinetics. The three-pool model is an expansion of the two-pool model and relies not only on the measurement of amino acid enrichments and concentrations in the arterial and venous blood, but also on the direct measurement of the amino acid enrichments in the free tissue water. This allows for the direct measurement of the *intracellular* amino acid

kinetics, including recycling from breakdown to synthesis. In addition, it also allows for calculation of the amino acid transport rates from artery into the muscle tissue, and from the muscle tissue into the venous blood. Many of the human studies on the effects of insulin on muscle protein turnover have utilized the two-pool method [7,8,30,33–40,45,46], but most recently several studies have utilized the three-pool method either alone [31] or in conjunction with the two-pool and/or the precursor product method [7,8,45,46]. In those studies in which more than one model was used the results of the two- and three-pool model tended to be consistent, while the results of the arteriovenous balance methods and the precursor-product method not always agreed possibly due to the different timing of the measurements [7]. Samples for the arteriovenous methods are in fact collected in a shorter time frame as compared to samples for the precursor-product method. The latter involves measurement of the incorporation rate of an amino acid tracer into muscle proteins and provides an integrated view of the overall effect of insulin on muscle protein synthesis over several hours.

A second and, possibly, more important issue to be considered is differences in study design that may have differentially emphasized the complex mechanisms by which insulin exerts its action on muscle protein metabolism. Specifically, a review of the human studies on the effects of insulin on skeletal muscle protein turnover suggests that such conflicting results could be entirely explained by differences in amino acid availability during insulin infusion. The studies reporting an increase in skeletal muscle protein synthesis as the primary mechanism of the insulin-induced muscle protein anabolism also reported an increase in amino acid availability [7,31,32,37–42]. Conversely, the studies that found a significant reduction in skeletal muscle protein breakdown with no significant changes in protein synthesis during hyperinsulinemia also reported a decrease or no change in amino acid availability [7,30,33–36,41]. The differences in amino acid delivery and availability were due to differences in amino acid concentrations and blood flow. The changes in amino acid concentrations were determined by the modality of insulin infusion, and/or by the concomitant infusion of exogenous amino acids, or lack of thereof. Specifically, systemic insulin infusion dramatically decreases blood amino acid concentrations [30,40] unless amino acids are replaced by exogenous infusion [30,34,37,39,40,47,48]. Conversely, local insulin infusion in a leg or a forearm allows for the exposure of muscle tissue to relatively high insulin levels while avoiding a major reduction in blood amino acid concentration [31,33]. As discussed in detail earlier, a fundamental variable that significantly affects the response of skeletal muscle protein synthesis to insulin is blood flow. Under physiologic conditions of normal amino acid concentrations, insulin has been reported to enhance microvascular flow [26,49], amino acid delivery to the muscle, and amino acid transport into the myofibers [7,8,31], with a resulting stimulation of skeletal muscle protein synthesis [7,8,31].

Third, it is also important to highlight that skeletal muscle protein metabolism is less sensitive to insulin as compared to glucose or fat metabolism, so that the stimulatory effect of insulin on skeletal muscle protein synthesis occurs only at or beyond physiologic postprandial levels of insulin concentrations (approximately $50\,\mu U\,mL^{-1}$ or $300\,pmol\,L^{-1}$) [7,31,37]. Lower insulin doses, such as doubling the basal insulin concentration (approximately $20–25\,\mu U\,mL^{-1}$ or $120–150\,pmol\,L^{-1}$), have no effect on protein synthesis [7,46] and may [46] or may not [7] decrease muscle protein breakdown.

Fourth, it is important to recognize that measures of skeletal muscle protein metabolism represent the combined result of the turnover of individual proteins. Animal studies have reported that insulin can differentially affect the synthesis of individual proteins in the skeletal muscle [50]. Future studies will have to explore the potential differential effects of insulin on individual skeletal muscle protein turnover.

Splanchnic tissues

Insulin may affect the protein turnover rates of splanchnic tissues, particularly the liver. However, most of the data rely on the measurement of export liver proteins because it is very difficult to measure parenchymal liver protein turnover in humans. The liver arteriovenous amino acid balance methods are not applicable in healthy humans due to the difficulty of obtaining portal venous blood. One study performed using the splanchnic arteriovenous balance technique with amino acid tracers in humans, that is, a technique that involves measurement of the amino acid and amino acid tracer balance across the entire splanchnic region (including both liver and intestine), did not report a major effect of insulin on these tissues [40]. However, stable isotope tracer methods cannot be accurately utilized with the splanchnic arteriovenous balance method because the liver can oxidize all circulating amino acids, thereby impeding the correct estimation of parenchymal liver protein synthesis. The arteriovenous model assumes that the disappearance of an amino acid occurs only via synthesis, which is not the case when amino acids are oxidized by the liver. The precursor-product method is also not applicable due to the invasiveness of the liver biopsy procedure. However, the precursor-product method can be used to measure the effect of insulin on the synthesis of liver export proteins, such as albumin and acute phase proteins. Using this technique it has been shown that insulin increases albumin synthesis in normal [51] and insulin-deficient diabetic subjects [52] while decreasing fibrinogen [51,52] and antithrombin III [51] synthesis. Increased amino acid availability enhances the response of albumin synthesis to insulin in normal humans [53], suggesting that anabolic mechanisms similar to those discussed for skeletal muscle are also present in the liver. Since insulin also stimulates the transcapillary escape of albumin, it has been hypothesized that the insulin-induced increase in albumin synthesis is another important anabolic mechanism to spare dietary amino acids from oxidation and deliver them to the peripheral tissues in form of albumin [53].

The negative effect of insulin on fibrinogen and antithrombin III synthesis may also explain why lack of insulin or insulin resistance accelerates fibrinogen synthesis and atherosclerosis in diabetes.

Skin

The skin makes up approximately 20% of the entire body mass and contributes significantly to whole body protein metabolism because of its relatively rapid protein turnover rate. However, data on the effects of insulin on skin physiology are sparse and obtained mainly in animals. Using stable isotope tracers and a rabbit model to measure the arteriovenous amino acid balance of the ear, which mainly represents skin protein metabolism [54], it has been shown that the skin net amino acid balance is not significantly different from zero. Insulin decreases the overall skin protein turnover [44]. Specifically, insulin decreased skin protein synthesis and breakdown to the same extent, resulting in no significant changes in net protein balance. Since skin protein synthesis has been shown to be dependent upon recycling of amino acids released by skin protein breakdown, it is likely that the main effect of insulin on skin protein turnover is initially a reduction in skin protein breakdown, which is then followed by a secondary decrease in skin protein synthesis. Interestingly, insulin becomes anabolic for skin proteins during wound healing [55]. Also this effect is attributable to a reduction in skin proteolysis, rather than an increase in skin protein synthesis.

Effects of insulin on whole body protein turnover

The effect of insulin on protein turnover at the tissue level is clearly anabolic. However, the basic mechanisms vary from tissue to tissue, with some tissues responding with an increase in protein synthesis and others with a decrease in protein breakdown. When the effect of insulin on protein metabolism is measured at the whole body level, the predominant anabolic effect is a reduction in protein breakdown rather than an increase in protein synthesis. This may seem surprising, given the results of the studies in human skeletal muscle and those in animals and cell systems indicating that insulin stimulates protein synthesis (see earlier sections on integrative physiology of insulin action and effects of insulin on protein metabolism). However, several studies performed measuring whole body leucine turnover in humans during systemic insulin infusion with euglycemic clamp have reported that insulin reduces whole body protein breakdown [56–58]. This effect is dose-dependent. When insulin concentrations are within the physiologic postprandial range protein breakdown as well as leucine oxidation are significantly reduced [56–60]. The insulin-induced decrease in protein breakdown reduces amino acid availability for synthesis. Conflicting results have been reported when amino acids are administered during hyperinsulinemia, with some

studies indicating an increase in whole body protein synthesis [53,61] while others report no changes [59,60].

The results of the whole body protein metabolism studies are at odds with those obtained in skeletal muscle and liver showing that insulin stimulates protein synthesis (see previous section "Effects of insulin on protein metabolism in specific tissues"), particularly if we consider that muscle and liver proteins are quantitatively important contributors to whole-body protein turnover. Limitations of the whole body technique to measure protein synthesis may provide a likely explanation for this inconsistency. Specifically, when leucine is utilized as a tracer, whole body protein synthesis is indirectly calculated as the difference between protein breakdown and leucine oxidation. However, the measurement of breakdown and oxidation is not precise due to several issues [43]. The most important is a main assumption underlying the tracer dilution model that each tissue contributes to the dilution of the leucine tracer in the blood proportionally to the individual tissue protein breakdown rate. However, this assumption is not valid because insulin exerts differential effects on protein breakdown in the various tissues (see previous section on effects of insulin on protein metabolism). In addition, insulin can affect amino acid transport [9], resulting in a differential release of free amino acids by the various tissues, which further impacts blood leucine enrichment. Calculation of leucine oxidation also requires the assumption that blood leucine enrichment or blood alpha-ketoisocaproate enrichment represents the enrichment of the true precursor for oxidation, which, for the reasons just mentioned, is probably not correct. Thus, the estimation of whole body protein synthesis from the difference between two imprecise measures, whole body protein breakdown and amino acid oxidation, can amplify the error and lead to incorrect conclusions. However, it is also possible that insulin inhibits the synthesis of enough, unmeasured proteins to offset its stimulatory effect on skeletal muscle and liver protein synthesis. Future studies focusing on the effect of insulin on the synthesis of individual proteins are warranted.

Pathophysiology of insulin action on protein metabolism

In the following sections we provide a brief summary of the changes that common conditions induce on the response of protein metabolism to insulin.

Aging

There is growing evidence [9,10,42,45] that healthy aging per se reduces the muscle protein anabolic action of insulin in nondiabetic older persons. This anabolic resistance to insulin likely contributes to sarcopenia, the loss of skeletal muscle mass and function with aging, and frailty in older adults [62]. The skeletal muscle anabolic resistance to insulin is associated with decreased insulin-induced vasodilation and a reduction

in amino acid delivery and transport into the muscle, which prevent the physiologic activation of mTORC1 signaling and protein synthesis [9,10,42,45]. This is a true insulin resistance, because it is overcome by supraphysiologic insulin concentrations [45]. Endothelial dysfunction is its main driver, as pharmacologic vasodilation with sodium nitroprusside restores the anabolic response of muscle protein synthesis to insulin in healthy older subjects [10]. However, vasodilation alone, in the absence of hyperinsulinemia, does not stimulate mTORC1 and muscle protein synthesis [27]. This suggests that skeletal muscle insulin signaling must also be activated to stimulate protein anabolism.

Physical activity

Physical activity can influence the effect of insulin on protein metabolism. Aerobic exercise can overcome the insulin resistance of skeletal muscle protein metabolism in older adults by improving endothelial function and mTORC1 signaling [63,64]. Vice versa, insulin enhances the positive effect of resistance exercise on muscle protein anabolism by reducing the post-exercise increase in muscle protein breakdown [65].

Protein metabolism in diabetes

Protein metabolism is significantly altered by diabetes. We provide in the following sections a summary of the changes that occur in type 1 and type 2 diabetes as well as in critical illness, a condition of severe insulin resistance.

Type 1 diabetes mellitus

Uncontrolled type 1 diabetes has profound catabolic effects on nitrogen balance and protein metabolism. Immediately after the discovery of insulin in the 1930s, Atchley et al. demonstrated how insulin deficiency severely impacts nitrogen metabolism by inducing nitrogen loss and resulting in a profoundly negative nitrogen balance, an indication of net protein catabolism [66]. More recently, studies on leucine turnover have shown that the net protein catabolism induced by insulin deprivation is due to an increase in whole body protein breakdown [67–73]. Type 1 diabetes was also found to be associated with increased leucine oxidation during insulin deficiency [67–72]. A higher oxidation rate is indicative of an increased net loss of essential amino acids [67–72]. Surprisingly, in the same insulin-deprived type 1 diabetic patients the nonoxidative utilization of leucine (nonoxidative leucine disposal), which is an indicator of whole body protein synthesis, was reported to be normal or increased [67–72]. The puzzling results of a normal or quasi-normal whole body protein synthesis during insulin deficiency in the context of severe nitrogen loss may be due to a methodological artifact, because the protein synthesis values were indirectly calculated as the difference between whole body leucine flux and leucine oxidation. However, skeletal muscle protein synthesis,

directly measured with tracers, was reported to be normal in insulin-deficient type 1 diabetes patients [69] or decreased in streptozotocin diabetic rats [74]. Thus, if the observed increase in whole body protein synthesis with insulin deficiency is real and not due to a methodological artifact, it raises the question of where this increase occurs. Several studies have highlighted that insulin can differentially affect the synthesis rate of liver secretory proteins [51,52,75–77] while reducing splanchnic protein synthesis [78]. Specifically, synthesis of the acute phase response proteins has been reported to increase during insulin deficiency [52,75–77].

Type 2 diabetes mellitus

The main hallmark of type 2 diabetes mellitus is a global insulin resistance which includes a reduction in skeletal muscle insulin signaling [79]. Thus, type 2 diabetes has the potential to impact protein homeostasis. Specifically, type 2 diabetes is characterized by impaired insulin sensitivity. Particularly relevant for protein metabolism is the reduction in insulin signaling through the PI3K pathway that occurs with type 2 diabetes. The PI3K pathway is essential to transport insulin across the endothelium to the target tissues. Moreover, PI3K is an upstream stimulator of Akt, which activates mTORC1. In turn, mTORC1 stimulates amino acid transporter expression via ATF4 (see earlier section on integrative physiology of insulin action). Thus, impaired insulin signaling could decrease amino acid transport into the muscle cell and blunt muscle protein synthesis. A very limited number of studies have addressed the effects of type 2 diabetes on protein metabolism. In young and middle-aged adults, poorly controlled type 2 diabetes has been reported to increase whole body [80] and muscle protein turnover [81], and induce a net nitrogen loss [82]. However, other studies have not confirmed those findings [83–85]. Poorly controlled type 2 diabetes in young adults does not significantly impact the basal muscle protein synthesis rate, while it increases leucine nitrogen flux and protein breakdown [81,85]. These changes can be corrected by hyperinsulinemia [81,86]. Data in older adults with type 2 diabetes are even scantier. One study reported no differences between healthy and type 2 diabetes older adults in the response of muscle protein synthesis to a mixed meal [87]. However, the meal contained a very large amount of protein (more than 100 grams), and the results were also confounded by the use of various glucose-lowering medications in some of the subjects. Independent observational studies have recently reported that type 2 diabetes accelerates the loss of muscle mass and strength in older persons, even after adjustment for comorbidities and other factors [88–91]. Another cohort study reported that insulin sensitizers may slow down the rate of decline of muscle mass in older men with type 2 diabetes [92], suggesting an important role for insulin resistance in this process. Altogether these data suggest that type 2 diabetes may have negative effects on protein metabolism particularly in older adults.

Critical illness

Critical illness is associated with severe insulin resistance result-
ing in hyperglycemia. However, this insulin resistance does not
translate into resistance to the protein anabolic action of insulin,
as insulin infusion can still suppress whole body protein break-
down [93] and increase muscle protein synthesis [94] in criti-
cally ill patients.

Conclusions

Insulin is a major protein anabolic hormone that promotes
dietary amino acid storage in the fed state and exerts an
anticatabolic role in the basal state and during critical illness.
The mechanisms by which insulin exerts its anabolic action are
complex and challenging to study because insulin is normally
secreted during feeding. Thus, it very difficult to isolate the
insulin effect from that of increased nutrient and energy
availability. Moreover, methodological issues further complicate
the precise measurement of the effects of insulin on protein
turnover.

   In general, the effects of insulin are tissue specific, increasing
protein synthesis in some tissues, such as skeletal muscle, and
reducing protein breakdown in others, such as the skin. In sev-
eral instances insulin's effect is also protein specific. For example
it increases the synthesis of some liver export proteins, such as
albumin, and may reduce the synthesis of others, such as fib-
rinogen. These effects can be magnified or reduced by specific
pathophysiologic conditions, such as exercise, diabetes, or criti-
cal illness.

Lipid and lipoprotein metabolism, hypolipidemic agents, and therapeutic goals

Gissette Reyes-Soffer and Henry N. Ginsberg

Department of Medicine, Columbia University College of Physicians and Surgeons, New York, NY, USA

Key points

- Diabetic dyslipidemia includes elevated triglyceride levels, low levels of high-density lipoprotein cholesterol, and small cholesterol-depleted low-density lipoproteins.
- Insulin resistance is the main underlying abnormality causing diabetic dyslipidemia.
- The dyslipidemia is found in prediabetics and people with type 2 diabetes mellitus.

Introduction

Any discussion of lipid and lipoprotein metabolism in diabetes mellitus, especially type 2 diabetes mellitus (T2DM), must consider the role of insulin resistance (IR). IR plays a central role in the abnormal lipid and lipoprotein metabolism of T2DM [1] as evidenced by the characteristic set of lipid and lipoprotein abnormalities accompanying IR, even in the absence of frank hyperglycemia or abnormal glucose tolerance. Individuals with IR have low plasma levels of HDL-C and elevations in plasma triglyceride (TG) levels compared with levels seen in individuals who have normal insulin sensitivity. There is also an increase in the proportion of low-density lipoprotein (LDL) particles that are small, dense, and cholesterol ester-poor. Importantly, total cholesterol levels in insulin-resistant individuals are generally comparable to levels in people who are insulin sensitive, reinforcing the need for more detailed measures of lipoprotein to assess CVD risk [2–4]. Lipid derangements seen with IR progressively worsen across a continuum of declining glucose tolerance, from normal glucose tolerance (NGT) through impaired glucose tolerance (IGT) and T2DM [5]. Importantly, the relationship between IR and dyslipidemia extends across major ethnic groups, including African- and Hispanic Americans. Among women, IR and T2DM seem to exert a greater negative impact on several CVD risk factors, including TG and HDL-C levels and LDL particle size. This may, at least in part, account for the greater relative increase in coronary heart disease (CHD) risk observed in women with T2DM compared with their male counterparts [6].

IR and T2DM are also associated with increases in very low-density lipoprotein (VLDL) particle number and VLDL TG concentration, and a predominance of larger, more buoyant $VLDL_1$ particles. In contrast, HDL particle number and size decrease in the face of increasing IR [2,3,5]. Plasma levels of apolipoprotein B100 (apo B100), the defining protein of the atherogenic lipoprotein series, which includes VLDL, intermediate-density lipoproteins (IDL), and LDL, are increased in the setting of IR [1]. This is particularly true when hypertriglyceridemia is also present, as is usually the case in individuals with IR or T2DM. In contrast, plasma levels of apolipoprotein A1 (apo A1), the surface protein unique to HDL particles, are reduced with IR [1].

The derangements in lipid and lipoprotein physiology discussed thus far occur in the context of the fasting state. Importantly, however, IR and T2DM are also associated with disordered postprandial lipid metabolism [7]. Although the severity of postprandial hyperlipidemia is typically closely related to the fasting plasma TG level [7], postprandial dyslipidemia has been demonstrated in people with T2DM even in the setting of normal fasting TG levels and optimal blood glucose control [8]. Although postprandial dyslipidemia has been associated with increased CVD prevalence in individuals without diabetes [7,9,10], this relationship has not been well characterized in people with IR or T2DM [7,11]. Importantly, a study in 150 individual with diabetes with or without coronary artery disease (CAD) demonstrated no differences in several aspects of postprandial lipid and lipoprotein levels [12]. This is probably indicative of the nearly universal abnormalities of postprandial lipid metabolism in T2DM. On the other hand,

several recent studies in large cohorts, most without diabetes, have demonstrated that nonfasting TG levels are as predictive or even more predictive of future CVD events than fasting TG concentrations [13,14].

Lipoprotein metabolism in normal individuals and in type 2 diabetes mellitus

Key points: Triglyceride levels in blood are regulated by the size and number of VLDL secreted from the liver and the efficiency with which triglycerides are cleared from the plasma by lipoprotein lipases. In T2DM, greater numbers of larger, more triglyceride-enriched VLDL are secreted from the liver and lipoprotein lipase activity may be modestly reduced; both lead to increased levels of triglyceride in the blood. HDL cholesterol levels are reduced for several reasons, including increased transfer of that cholesterol to very low- and low-density lipoprotein, in exchange for their triglyceride, by cholesterol ester transfer protein. LDL particles lose some of their cholesterol to VLDL via the same exchange mechanism, which generate smaller, denser, LDL.

Lipoproteins are macromolecular complexes consisting of core lipids, mainly TG and cholesteryl esters (CEs), and surface phospholipids, free cholesterol, and one or more apolipoproteins. Five distinct major classes of lipoproteins have been characterized based on physical characteristics, including separation by ultracentrifugation, molecular weight, diameter, and chemical composition. Lipoprotein subclasses have been further defined based on subtle differences in physical and chemical properties. Notably, in addition to providing structural stability, the surface apolipoproteins impart critical functions to their respective lipoprotein particles [15].

Assembly and secretion of chylomicrons, which are the largest and most TG-enriched lipoprotein particles, occur in the postprandial state, when dietary TGs and CEs must be transferred from enterocytes of the small intestine into the circulation. The assembly and secretion of chylomicrons by the enterocyte is in several ways analogous to VLDL assembly and secretion by the hepatocyte: whereas apo B100 is the necessary, prototypic surface protein associated with VLDL, IDL and LDL, apo B48, a truncated form of apo B100, plays the same role for chylomicrons. Microsomal triglyceride transfer protein (MTP) packages apo B48 with core lipids and is essential to the formation of chylomicrons. Newly assembled chylomicrons, also carrying apolipoproteins A1 and A4, are secreted into the lymphatic system and eventually enter the venous circulation [15]. Studies in animal models of IR and/or diabetes have demonstrated increased intestinal secretion of apo B48-containing lipoproteins, accompanied by increased expression, mass and activity of intestinal MTP [16] and, under certain dietary conditions, an increase in intestinal *de novo* lipogenesis, likely mediated through activation of a major transcription factor, the sterol response element binding protein

1c (SREBP-1c) [16]. Moreover, studies of men with varying degrees of IR or with T2DM demonstrated increased intestinal production of apo B48-containing TG-rich lipoprotein (TRL) particles [17]. Increased intestinal expression of MTP in people with T2DM may also play a role here. Lewis and Adeli and their colleagues have furthered our knowledge of the assembly and secretion of apo B48-containing lipoproteins, including demonstration of inhibition of chylomicron secretion by acute administration of insulin and glucagon-like peptide 1 [18]. The conflicting effects of acute insulin and chronic hyperisulinemia in states of IR suggest that the latter also develops in the intestine.

After entering the plasma, chylomicrons acquire apolipoproteins C1, C2 and C3 (apo C1, apo C2 and apo C3) from the surface of HDL particles. Chylomicron clearance is largely mediated through hydrolysis of core TGs by adipose tissue-derived lipoprotein lipase (LpL) in a process that requires apo C2 as an activator of LpL. In contrast, apo C3 can inhibit LpL-mediated lipolysis. The activity of other factors, including apo A5, which appears to facilitate LpL-mediated lipolysis [19], and angiopoietins 3 and 4 [20,21], which inhibit lipolysis, may also regulate postprandial lipid metabolism. The breakdown of chylomicron TG releases fatty acids (FAs), which are taken up by the local tissue, and produces chylomicron remnant particles. These remnants acquire apolipoprotein E (apo E) from HDL particles and are also enriched in CEs derived from exchange of core lipids with LDL and HDL, the latter process being mediated by cholesteryl ester transfer protein (CETP). Ultimately, chylomicron remnant particles are cleared mainly by hepatic uptake through the interactions of apo E with the hepatic LDL receptor, the LDL receptor-related protein (LRP), and/or cell-surface heparan sulfate proteoglycans. Additionally, hepatic lipase (HL) further hydrolyzes chylomicron remnant particle TG and may augment uptake by the liver. Apo C1 and C3 modulate chylomicron clearance by the liver by interfering in the binding of apo E to its receptors [15].

IR and T2DM affect chylomicron and remnant metabolism negatively at several points in the schema described earlier. For example, there are modest decreases in LpL activity and increases in apo C3 relative to apo C2 levels. Increased apo C3 secretion into plasma has been demonstrated in patients with IR and hypertriglyceridemia [22,23], with impaired LpL-mediated lipolysis of chylomicron TG as well as decreased hepatic uptake of remnant particles the likely results. Recent studies with antisense to apo C3 in hypertriglyceridemia support the important role of this apoprotein in metabolism of TG-rich lipoproteins [24]. Clearance of chylomicrons is competitive with clearance of VLDL and so hepatic overproduction of TG-rich VLDL particles in T2DM can, itself, lead to reduced efficiency of chylomicron clearance [1]. This results in increases in circulating TRLs, which are known to be particularly atherogenic [25].

In the fasting state, hepatic VLDL assembly and secretion predominate. Utilization of nascent apo B100 for the assembly

and secretion of VLDL is, to a large extent, limited by substrate availability, namely TG, as apo B100 is constitutively synthesized [26]. In the presence of adequate TG, apo B100 is progressively lipidated through the actions of hepatic MTP, and the newly assembled VLDL particle is transported to the Golgi apparatus, where it may undergo further lipidation before secretion into plasma. The size of the nascent VLDL particles is also determined by TG availability, with a predominance of larger, more buoyant, more TG-enriched $VLDL_1$ and fewer smaller, denser $VLDL_2$ particles produced in the presence of excess hepatocyte TG. Decreased availability of core lipids and/or insufficient MTP activity can lead to both co- and posttranslational degradation of apo B100. Insulin can acutely target apo B100 for post-translational degradation and this may be important in the postprandial period. However, this effect may be significantly diminished in the presence of IR and concomitant chronic hyperinsulinemia and steatosis [27]. Thus, a combination of IR and excess hepatic TG availability results in increased hepatic secretion of both apo B100 and TG even when hyperinsulinemia is present [28–30]. Further complicating this scheme is the ER stress that develops in the presence of IR and fatty liver [31]; apo B100 degradation may be increased by ER stress, leading to less hepatic VLDL secretion and greater steatosis [32]. Thus, a combination of several factors common to IR and T2DM, including hyperinsulinemia, increased FAs, increased lipogenesis, steatosis, ER stress, and apoB degradation, will all play important roles in determining the quantity and size of VLDL secreted from the liver [33].

TG availability is a major driver of VLDL assembly and secretion. FA contribution to the hepatic TG pool is, therefore, a key regulator of that process. Circulating FAs from the peripheral tissues, notably from adipose tissue, FAs derived from chylomicron and VLDL remnant uptake by the liver, and FAs obtained through *de novo* hepatic lipogenesis are the three sources of hepatic FA for TG synthesis; the major source, by far, being circulating FA [34]. In states of IR and T2DM, all three sources increase hepatic FA [35]. FA flux to the liver is increased as a result of IR in adipocytes, and this can directly stimulate hepatic secretion of apo B-containing lipoproteins [36,37]. Elevated levels of apo B48- and apo B100-containing remnant particles provide TG for hepatic uptake [28]. *De novo* lipogenesis, the third source of hepatic TG, is likely upregulated via insulin-mediated stimulation of SREBP-1c, a major lipogenic transcription factor. Recent studies indicate that mTOR signaling, both via the mTORC1 and mTORC2 complexes, is central to the "selective" insulin response in the lipogenic pathway in an otherwise insulin-resistant liver [38]. If there is concomitant hyperglycemia, there will also be induction of another transcription factor, carbohydrate responsive element binding protein (ChREBP), which also activates genes required for lipogenesis [30]. Interestingly, the hepatic expression of another nuclear transcription factor, peroxisome proliferator-activated receptor γ (PPARγ), is increased in a number of mouse models of IR and dyslipidemia [39], as well as in humans with hepatic steatosis. In humans, nonalcoholic fatty liver disease (NAFLD),

which is closely associated with IR, is characterized by increased hepatic TG derived from *de novo* lipogenesis [34].

The fate of VLDL particles after secretion initially parallels that of chylomicrons; hydrolysis of VLDL TG by LpL, modulated by the relative proportions of apo C2 and apo C3. Additional regulation of LpL activity derives from the interactions of apo AV, which may facilitate the interaction of TG-rich lipoproteins with LpL at the endothelial cell surface [40] and the angiopoietin-like proteins (angptl3 and angptl4), which interfere with the activity of LpL [41]. Lipolysis of core TG yields smaller, denser VLDL remnants usually referred to as IDL; the efficiency of this process is impaired in the setting of T2DM. Hepatic uptake of VLDL remnants is similar to that of chylomicron remnants, except that VLDL remnants or IDL may undergo further metabolic modifications to generate LDL particles. HL is thought to play an important role in this process. However, despite the increased levels of HL observed with IR and T2DM, conversion of VLDL to LDL is typically reduced. LDL particles are primarily composed of core CEs associated with surface apo B100. As with VLDL remnants and IDL, clearance of LDL occurs mainly through hepatic LDL-receptor-mediated uptake. IR and poorly controlled T2DM can be associated with a reduction in LDL receptors, thereby limiting removal of these particles from the circulation [15,28].

LDL in the circulation can participate in CETP-mediated exchange of its core CE for VLDL or chylomicron TG, resulting in a TG-enriched, CE-depleted LDL particle. Subsequent lipolysis of the TG-enriched LDL particle by LpL or HL produces small, dense LDL. The characteristic hypertriglyceridemia of T2DM is associated, therefore, with the presence of small, dense LDL. It has also been proposed that the large $VLDL_1$ particles that predominate in the setting of T2DM hypertriglyceridemia are avid acceptors of CETP transferred CEs from HDL and preferentially undergo catabolism to give rise to small, dense LDL [15,42]. In addition, the increased HL activity observed in T2DM could play an important role in the production of small, dense LDL particles [15]. The role of small dense LDL has been a longstanding topic of debate, particularly as to whether they are more atherogenic than other apo B-containing lipoproteins [43,44].

The "anti-atherogenic" HDL differ considerably in structure and function from the apo B-containing lipoproteins. HDL begins as cholesterol-poor phospholipid discs containing surface apo A1 that is secreted by the liver and intestine. Transfer of intracellular or plasma membrane cholesterol to these nascent particles occurs via the transport protein, ATP-binding cassette transporter A1 (ABCA1). Studies by Parks and colleague demonstrated the critical role of hepatic ABCA1 in the maintenance of plasma HDL cholesterol concentration [45], but transfer of cholesterol from peripheral cells also contributes to HD. This transfer is coupled with cholesterol esterification by the enzyme lecithin:cholesterol acyltransferase (LCAT), accompanied by movement of the product CEs to the core of the maturing HDL_3 particle. Apo A1 mediates this process through its ability to activate LCAT. Repeated cycles

of this process, together with transfer of cell cholesterol to the maturing HDL particle via ATP-binding cassette transporter G1 (ABCG1) and scavenger receptor B1 (SRB1), give rise to mature, CE-rich HDL_2. Mature HDL particles can deliver both free and esterified cholesterol to the liver via interaction with SRB1 [1]. There may be other pathways for HDL uptake by the liver as well. The process just described, at least when the source of free cholesterol is a peripheral cell, has been called reverse cholesterol transport (RCT). It is believed, based on mainly mouse studies, the RCT from cholesterol-laden macrophages in the artery plaque, with eventual hepatic uptake and metabolism, is a critical function of HDL. The fate of apo A1 is less certain, but it is known that significant quantities are taken up and degraded by the kidneys and liver. If CETP-mediated exchange of core lipids is increased, as is the case in the dyslipidemia of T2DM, apo A1 dissociates from the smaller, triglyceride-rich HDL, and clearance of "free" apo A1 by the kidney follows, reducing the plasma apo A1 levels and HDL particle number [15,46].

Therapeutic approaches to the dyslipidemia of insulin resistance and type 2 diabetes mellitus

Key points: The rationale for treating the diabetic dyslipidemia is clear, it is associated with significantly increased risk of cardiovascular events. Weight loss, exercise, and diet modifications are key to successful treatment of all of the lipid abnormalities in patients with T2DM. Statins are the mainstay of therapy—they lower LDL cholesterol up to 50%, lower triglycerides about 15–25%, and have minimal effects of HDL cholesterol levels. Statins significantly lower cardiovascular events in people with diabetes. Benefits of treatment of high triglycerides and low levels of HDL cholesterol after reaching optimal treatment status with statins is unclear.

Rationale for treating LDL
Over the past 50 years, results from epidemiologic studies, animal models, and clinical trials have clearly demonstrated that elevated LDL-C is a major risk factor for CV morbidity and mortality [47]. In addition, it has been demonstrated that aggressively lowering LDL-C levels can decrease CV risk [48]. As a result, a system of guidelines for LDL goals for therapy developed over the past 25 years; a quick review of the progression of these guidelines was published recently [49].

Beginning in 2004, there had been a push to drive LDL-C goals lower and lower with the hope that this would lead to an improvement in CV outcomes. In fact the NCEP issued a "white paper" suggesting an even lower LDL-C goal of $<70\,mg\,dL^{-1}$ for patients at very high CV risk [50], and this was reiterated in the 2006 AHA/ACC guideline paper [51]. These reports were based in part on data from the Treating to New Targets (TNT) study, which demonstrated that intensive therapy with atorvastatin 80 mg compared with atorvastatin 10 mg significantly reduced the rate of major CV events by

22%. In TNT, the end-of-treatment mean LDL-C levels were $98.6\,mg\,dL^{-1}$ and $77\,mg\,dL^{-1}$ with atorvastatin 10 mg and 80 mg, respectively [52]. The results of the Pravastatin or Atorvastatin Evaluation and Infection Therapy — Thrombolysis in Myocardial Infarction 22 (PROVE-IT – TIMI 22) study [53], in which patients with acute coronary syndrome who had their LDL-C levels reduced to $62\,mg\,dL^{-1}$ fared better than those patients whose LDL-C was $95\,mg\,dL^{-1}$, support the TNT results.

Statin trials have also been conducted specifically in patients with T2DM. In the Collaborative Atorvastatin Diabetes Study (CARDS) trial, treatment with atorvastatin resulted in a significant reduction in major CV events irrespective of pretreatment cholesterol levels [54]. On the other hand, the Atorvastatin Study for Prevention of Coronary Heart Disease Endpoints in Non-Insulin-Dependent Diabetes Mellitus (ASPEN), which randomized patients with T2DM to receive 10 mg of atorvastatin or placebo in a 4-year study, did not demonstrate a significant reduction in the primary composite endpoint of CV death with atorvastatin treatment [55]. Several post hoc, subgroup analyses of large trials not specifically targeted to diabetics did show similar benefit in the latter groups; they will be reviewed further in this chapter.

The very recent AHA/ACC guidelines [56] suggested, however, major changes in the way healthcare professionals should lower blood cholesterol levels to reduce cardiovascular disease. A strong point was the change in the use of initial LDL-C levels as the approach to initiation of treatment to identification of four groups of individuals whose risk was high enough to be considered for statin therapy: those with LDL-C $>190\,mg\,dL^{-1}$; those with prior CVD; those with diabetes and LDL-C $\geq70\leq190\,mg\,dL^{-1}$; those without CVD or diabetes but an LDL-C $\geq70\leq190\,mg\,dL^{-1}$ who have a 10-year risk for CVD $\geq7.5\%$. The new guidelines do not use MetS as a criteria for statin therapy. Clearly, the presence of diabetes is a major factor in these new guidelines. The new guidelines then declared that there were no data from randomized clinical trials (RCTs) to support the use of LDL-C goals to determine the intensity of treatment. The guidelines panel concluded that use of statins was supported strongly by RCT results and that high-intensity treatment was appropriate in most cases, particularly in patients with diabetes. However, the panel found no evidence for the use of non-statin drugs as "add-on" treatment to statins [56]. The new guidelines have, as may be expected, generated significant controversy. In particular, the conclusion that there is no evidence that "lower is better" is thought by some to fly in the face of the trials noted above in this section as well as the meta-analyses of the statin trials [48], epidemiologic data, animal-based studies, and natural genetic examples.

Rationale for treating HDL and TG
While LDL-C remains a primary target of cholesterol-modifying therapy for the primary and secondary prevention of CVD in the general population and among people with DM, HDL-C and TG have been given high importance, especially in higher risk

individuals [25,47]. The characteristically elevated TG levels and decreased HDL-C with IR, in the presence or absence of T2DM [2,3,5] led to the recommendation that non-HDL-C (total cholesterol - HDL-C) be considered a surrogate marker for the apo B100-containing lipoproteins [57,58]. The new AHA/ACC guidelines [56] concluded, however, that there is no evidence to target either LDL-C or non-HDL-C. The new guidelines also stated that other targets, such as TG or HDL-C have no support based on RCT; in fact, data from two trials where niacin was added to statins, Aim High [59] and HPS2-THRIVE (not yet published), and one in which fenofibrate was added to statin therapy, ACCORD [60], indicate no overall benefit compared to patients treated with statins alone. The ADA on the other hand, emphasizes the prime importance of attaining target LDL-C levels, but employs a different approach to the management of TGs and HDL-C (Table 17.1). The ADA guidelines recommend lowering TG levels to <150 mg dL^{-1} and include gender-specific HDL-C goals; namely, >40 mg dL^{-1} in men and >50 mg dL^{-1} in women [61–63].

With the AHA/ACC and ADA guidelines at odds, it is valuable to review the rationale for treatment to improve HDL-C levels in people with IR or T2DM. First, there is evidence from numerous epidemiologic studies in which low HDL-C is an independent predictor of CHD morbidity and mortality, including studies involving large numbers of people with IR or T2DM [64]. Second, evidence from prospective intervention trials and secondary analyses has suggested a benefit of raising

Table 17.1 American Diabetes Association dyslipidemia treatment goals and recommendations for adults with diabetes [62]

Treatment goals
- LDL-C
  - In patients without overt CVD:
    - Primary goal is LDL-C <100 mg dL^{-1}
    - Decrease LDL-C by 30–40% in patients >40 years of age regardless of baseline LDL-C
  - In patients with overt CVD:
    - Treat with statin to decrease LDL-C by 30–40%
    - Option: treat with high-dose statin to reduce LDL-C to <70 mg dL^{-1}
- Decrease TG to <150 mg dL^{-1}
- Increase HDL-C to >40 mg dL^{-1}; consider increasing HDL-C to >50 mg dL^{-1} in women

Treatment recommendations
- Medical nutrition therapy
  - Weight loss in overweight and obese individuals
  - Diet with reduced intake of total fat (~30% of total calories), saturated fat (<7% of total calories), and *trans* fatty acids (minimal); cholesterol <200 mg day^{-1}
  - Increased exercise
  - Smoking cessation
- Pharmacologic therapy
  - Statin therapy to decrease LDL-C
  - Fibrate therapy to decrease TG and increase HDL-C
  - Combination therapy with statin and another agent if necessary to achieve lipid targets

Source: Buse 2007 [62].

HDL-C levels on the risk of CHD events, independent of changes in other lipid and nonlipid risk factors [65]. Of note, a post hoc analysis of the Bezafibrate Infarction Prevention (BIP) Study focusing on the subgroup of participants with the MetS revealed a reduced incidence in MI associated with significant improvements in HDL-C and TG levels [66]. Furthermore, in that analysis a cardiac mortality benefit was demonstrated among subjects having "augmented" (i.e., four or five) features of the MetS, as defined by the ATP III. In VA-HIT, where increases in HDL-C were predictive of reductions in CV endpoints in the group treated with gemfibrozil [65], the greatest overall benefit of treatment was observed in subgroups with IR, with or without T2DM [67]. On the other hand, the recent negative niacin trials, Aim High [59] and HPS2-THRIVE, do not support the use of adding niacin to statin therapy. A subgroup, post hoc analysis of Aim High did suggest, nonsignificantly, that participants with high TG and low HDL-C at baseline did benefit [68].

Data regarding the independent effects of plasma TG levels on CHD risk are even more controversial, partly due to the close interrelationships between levels of TGs and the atherogenic apo B-containing lipoproteins. TG levels have nevertheless been shown to predict CHD risk in observational studies [69]. However, in the largest cohort study to date, Danesh and colleagues found that while TG was a strong predictor of CVD outcomes in more than 300,000 people, it lost all predictive power after adjustments for both HDL and non-HDL cholesterol [70]. One could argue, however, that adjustment for non-HDL, which contains cholesterol carried in TG-rich lipoprotein, is not a valid approach. In several clinical trials, stratification of individuals by TG and HDL-C levels has revealed higher risk subgroups with dyslipidemia that have benefited most from LDL-C-lowering interventions with respect to CHD risk reduction [71]. The FIELD Trial, in which 10,000 diabetics were randomized to placebo or fenofibrate, did not show an overall CVD benefit for the fenofibrate-treated group. However, a subgroup with baseline TG over 200 mg dL^{-1} and HDL-C less than 40 mg dL^{-1} showed a 30% reduction in the combined primary endpoint of CAD death and nonfatal myocardial infarction [72]. Similarly, in the ACCORD Lipid Trial, which was negative overall, 17% of the subjects with baseline TG in the upper tertile (>200 mg dL^{-1}) and HDL-C in the lower tertile (<34 mg dL^{-1}) had a 28% reduction in the primary endpoint of nonfatal myocardial infarction, nonfatal stroke, and CVD death [60]. On the other hand, no clinical trials thus far have demonstrated an independent relationship between TG-lowering and CHD risk reduction, including VA-HIT, where TG levels fell 31%.

As mentioned earlier, it is worth noting that postprandial lipemia has been associated with CAD in individuals without DM, whereas the evidence is less convincing or absent in individuals with IR or DM [7]. Data from two cross-sectional studies do not support an association between postprandial lipemia and the presence of CAD among people with T2DM [12]. Another small study suggests that postprandial numbers of

small remnant particles may contribute to the severity of angiographic CAD in T2DM [73]. Larger prospective studies are needed before recommendations can be made regarding the potential utility of postprandial hyperlipidemia as a predictor of CV risk in IR or DM. This, along with the lack of simple, clinically useful uniform measures of postprandial lipemia, explains the lack of guidelines for therapy of postprandial hyperlipidemia.

Treatment options
Diet and lifestyle modification
Appropriate lifestyle interventions involving diet and exercise can lead to weight loss, and since obesity is a major contributor to the IR and T2DM, weight loss should provide significant benefits to individuals with these problems. The Diabetes Prevention Program [74] demonstrated that a 6% weight loss and the addition of two hours of exercise per week was associated with a 58% reduction in the incidence of new T2DM in a group with IGT. Similar results were obtained in the Finnish Diabetes Prevention Study using similar interventions [75]. The 1-year results of Look AHEAD (Action for Health in Diabetes), a study of weight loss and diet in overweight and obese individuals, reported that intensive lifestyle intervention resulted in clinically significant weight loss in people with T2DM [76]. Participants in the intensive lifestyle intervention group achieved an average loss of 8.6% of initial body weight and a 21% improvement in CV fitness. These participants had a significantly greater decrease in the number of medicines used to treat their DM and blood pressure as well as a greater improvement in glycemic control when compared with participants receiving only diabetes support and education. These results, for the most part, withstood the demands of a 10-year follow-up, although the primary endpoint, decreased mortality in the intensive intervention group, was not reached [77].

In addition to simply reducing caloric intake, interventions that alter the nutrient composition of the diet may have benefits on risk factors for CVD and T2DM. There has been much debate, however, both in the popular press and in the medical community, regarding which diet strategy is most effective for both weight loss and reductions in CV risk. Conclusions that may be drawn from these diet interventions must be considered with the following caveat: We do not know if the changes that we see in plasma TG levels and, in particular, in HDL-C concentrations, are indicative of changes in risk for CVD. We are, in fact, extrapolating from large epidemiologic databases that show that increased TG and reduced HDL-C levels are associated with increased CV risk; this extrapolation remains to be proven in a clinical trial with dietary intervention.

Pharmacologic therapy
Before discussing in detail specific pharmacologic therapies, it is important to note that improving glycemic control in T2DM can result in mild to modest improvement in the dyslipidemia of diabetes. This is particularly true for hypertriglyceridemia in the setting of poor glycemic control; furthermore, the degree of TG-lowering may be related to the magnitude of improvement in glycemia. Concomitant with optimization of glucose control, therapeutic lifestyle changes (TLC), including dietary modification, weight reduction, and regular physical activity, should be initiated prior to, or simultaneously with, pharmacologic therapy. Pharmacologic therapy for dyslipidemia should be considered in the context of these changes [61,63,78]. Additionally, it must be noted that the new AHA/ACC guidelines for the treatment of cholesterol support the use of statins in several high-risk groups but do not support additional medications in combination with statins [56]. The new guidelines do allow non-statin drugs for patients intolerant to statins and for individuals with initial LDL-C levels greater than $190\,mg\,dL^{-1}$ (usually with familial hypercholesterolemia). It is noteworthy that the ADA/ACC guidelines for the management of lipoproteins in patients with cardiometabolic risk (which includes people with diabetes), while supporting the addition of non-statin drugs for people not at LDL-C goal on statin monotherapy, provided little support for non-statin drugs for the treatment of TG and HDL-C abnormalities [63].

3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase inhibitors
The HMG CoA reductase inhibitors, or "statins," are the most effective pharmacologic agents for reducing LDL-C concentrations and should be considered first-line therapy for this purpose, both in individuals with and without T2DM [48,63]. Several agents are available for clinical use, including lovastatin, fluvastatin, pravastatin, simvastatin, atorvastatin, rosuvastatin, and pitavastatin. As a class, they produce LDL-C reductions of 18–55%, with more modest changes in HDL-C and TG levels (5–15% elevations and 7–30% reductions, respectively) [79]. The new AHA/ACC guidelines suggest high-intensity statin therapy for most individuals with diabetes.

The effectiveness of statin therapy in primary and secondary CV risk reduction in both the general population with hypercholesterolemia and in people with diabetes is extremely strong (Table 17.2) [48,62]. Included in the meta-analyses were data from the following trials: The CARDS, a primary prevention study of 2838 participants with T2DM, demonstrated a statistically significant 37% reduction in major CV events among participants on low-dose atorvastatin treatment [54]. The Medical Research Council/British Heart Foundation Heart Protection Study (MRC/BHF HPS) included a large cohort of participants with T2DM, approximately half of whom had no evidence of existing coronary or other occlusive arterial disease [80]. Simvastatin therapy produced substantial reductions in the risk of coronary events, stroke and revascularizations in participants with DM, irrespective of pre-existing occlusive arterial disease or lipid concentrations. Further support was added by a subgroup analysis of the Long-Term Intervention with Pravastatin in Ischemic Disease (LIPID) trial, which demonstrated a reduction in CV events, including stroke,

Table 17.2 Major placebo-controlled clinical trials of statin therapy in patients with type 2 diabetes mellitus

Trial	n (DM)	Statin	Years	Change from baseline, %			CHD event* rate		RRR, %	P for RRR	ARR, %	NNT

in participants with IFG or T2DM and established CHD [81]. Moreover, the absolute risk reductions seen in those with IFG or T2DM were greater than those seen in the overall study population. These findings were supported and extended by the results of post hoc analyses of participants with IFG or DM in the Scandinavian Simvastatin Survival Study (4S) [82]. Another post hoc analysis demonstrated an increased risk of CHD events and greater benefit with simvastatin therapy among 4S participants with low HDL-C and elevated TG accompanying elevated LDL-C levels at baseline, compared with participants with isolated elevations in pretreatment LDL-C [71]. The Cholesterol and Recurrent Events (CARE) trial demonstrated a beneficial effect of pravastatin treatment on coronary outcomes in the overall study population as well as in the subgroups with DM or IFG, the latter being defined in that study by fasting glucose levels between 110 to 125 mg dL^{-1} [83]. Finally, a post hoc analysis of the TNT study that examined those participants who met the ATP III criteria for the MetS, but excluded individuals with T2DM, suggested an incremental benefit of high-dose atorvastatin therapy in this group [84].

The ASPEN trial, which included primary and secondary prevention participants, did not, however, demonstrate a significant reduction in the primary composite endpoint with atorvastatin [55]. The negative finding was attributed to certain features of the study design, as well as to changes in lipid treatment guidelines during the course of the study that necessitated protocol changes. Similarly, statin therapy did not impart a benefit with regard to coronary events in the subgroup of participants with T2DM in the Anglo-Scandinavian Cardiac Outcomes Trial—Lipid-Lowering Arm (ASCOT-LLA) [85]. The lack of benefit was ascribed to a low coronary event rate, a result stemming in part from the early cessation of the trial because of a marked benefit of statin therapy in the general study population. In the nonblinded Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT-LLT), the lack of effect with pravastatin therapy in participants with T2DM is believed to be due to the high usage of lipid-lowering therapy in the "usual care" control group, resulting in a smaller differential in LDL-C levels between the statin and control groups compared with that seen in other large statin trials [86].

A recent issue that must be addressed is how to balance aggressive statin treatment with recent data indicating an increase in risk for new diabetes in individuals receiving statins in large clinical trials. Although an early report from the WOSCOPS suggested that statins may prevent incident diabetes, JUPITER found the opposite, with a rate of incident diabetes of 30% in the rosuvastatin group versus 2% in the placebo group [87]. Several meta-analyses since then have indicated that statin treatment is associated with about a 9% increase in new diabetes [88] and that this risk is greater in people receiving higher doses of statins [89] as well as in people with more criteria for the MetS [90]. The meta-analyses presented to date do not suggest heterogeneity in the effects of different statins on incident diabetes, although some small, short-term studies indicate that certain statins may be less likely to raise blood glucose or HbA1c levels. In any event, it is clear that the benefit of statins in lowering CVD events far outweighs the risk of new onset T2DM in high risk and secondary prevention patients. Obviously, a risk for new onset diabetes is not relevant in people with diabetes, but health professionals should consider these new data because they indicate that control of existing diabetes is likely to worsen modestly due to long-term statin therapy.

Many "lipid/diabetes experts" believe that the greatest potential value of statin therapy in the treatment of the dyslipidemia of T2DM would be in combination with other lipid-modifying agents. This would clearly be the case when LDL-C-lowering to levels below 70 mg dL^{-1} is considered an appropriate goal,

for example, in patients with T2DM who have CVD or multiple poorly controlled risk factors [50]. This view is now dependent on whether one accepts the newest AHA/ACC guidelines [56] or the ADA/ACC guidelines [63]. For those following the ADA recommendations, LDL-C below 79 mg dL^{-1} may be attained through up-titration of statin doses or through combination with other agents, such as plant stanol and sterol esters, bile acid-binding resins and inhibitors of enteral cholesterol absorption. However, neither guideline give much support for the addition of niacin or peroxisome proliferator-activated receptor α (PPARα) agonists to statins.

Nicotinic acid

Nicotinic acid (niacin) has been used for more than 50 years to lower LDL-C and TGs, and increase the level of HDL-C. Indeed, niacin is the most potent HDL-C-raising pharmacologic agent available. Of note, we still, at this late time in the life of niacin, do not have definitive evidence regarding its mechanism(s) at the molecular level [91].

Niacin is available in short-acting and extended-release forms and is typically associated with increases in HDL-C of 15–35%, with 20–35% reductions in TG levels [92]. In contrast, it has a more modest effect on LDL-C levels, with reductions in the range of 10–20%. For this reason, it is not recommended as first-line therapy for LDL-C-lowering. It is, however, suggested for use as monotherapy in individuals with the diabetic lipid phenotype but without concomitant elevations of LDL-C. For people who exhibit elevated LDL-C in addition to abnormal HDL-C and TG levels, niacin can be used in combination with statins, or other LDL-C-lowering agents. Niacin can also reduce levels of lipoprotein (a) between 15–25%.

Despite the array of potentially beneficial effects on plasma lipids, the role of niacin has now been significantly diminished as an agent to prevent CVD. As described earlier, two recent completely negative trials where niacin was added to statin, far outweigh the positive outcome in the Coronary Drug Project (CDP) where niacin was given as monotherapy. In addition, niacin is associated with glucose intolerance and hyperglycemia, particularly at higher doses. The basis for these adverse effects on carbohydrate metabolism appears to result from niacin-induced IR [93]. Increased incident diabetes and worsening of existing diabetes was evident in HPS2-THRIVe [94].

At the present time, niacin treatment should be limited to individuals with familial hypercholesterolemia who do not reach goals on statins and other agents and possibly in statin-intolerant patients at low risk for diabetes. Physicians wishing to use niacin in other situations, that is, in patients with very low levels of HDL-C or high levels of Lp (a), must consider the absence of evidence for benefit.

Bile acid sequestrants (BAS)

This is another class of agents that have long been used in the management of lipid disorders. They have also been successful in monotherapy RCTs for preventing cardiovascular events [95].

In the United States, currently available drugs in this category include cholestyramine, colestipol and colesevelam. BAS lower LDL-C by reducing the enterohepatic return of cholesterol to the liver, leading to increased use of hepatic cholesterol for the bile acid synthesis pathway and consequent lowering of hepatic cholesterol content. The latter leads to upregulation of hepatic LDL receptors, which in turn lowers LDL-C levels. Typical improvements seen with BAS therapy include 15–30% reductions in LDL-C and smaller increases in HDL-C, in the order of 3–5%. In some cases, therapy with agents in this class increases hepatic VLDL production, thereby increasing plasma TG levels and worsening hypertriglyceridemia. These drugs should therefore be avoided in individuals with severe hypertriglyceridemia (TG > 400 mg dL^{-1}), and caution should be exercised when considering bile acid sequestrants for LDL-C-lowering in patients with moderately elevated TG levels (TG > 200 mg dL^{-1}), a group that encompasses a considerable number of people with T2DM. In addition, BAS should be avoided in patients with DM complicated by autonomic neuropathy and constipation, due to the gastrointestinal side effects associated with these drugs, particularly cholestyramine and colestipol. Use of ezetimibe as an adjunct to statin treatment would depend on whether one believes in the AHA/ACC or the ADA/ACC guidelines for lowering LDL-C.

Over the past several years, there has been a renewed interest in BAS, especially as a potential LDL-C-lowering agent in people with diabetes. Preclinical studies of the role of farnesoid X receptor (FXR) in the regulation of carbohydrate metabolism have raised interest in the glucose-lowering effects of BAS [96]. Of note, glucose levels improved and there were reductions in HbA1c levels in the range of 0.4% in a recent study with colesevelam [97]. Indeed, colesevalem received an indication from the FDA for glucose lowering.

Cholesterol absorption inhibitors

Ezetimibe was the first available agent in a new class of molecules that interferes with cholesterol absorption by selectively inhibiting the uptake of cholesterol from the intestinal lumen at the level of the brush border of the enterocyte; for a number of reasons, it remains the only available agent in this class. A multicenter, randomized, double-blind, placebo-controlled trial demonstrated that ezetimibe 10 mg decreased LDL-C by 17–20% compared with placebo [98]. It has small effects on TG and HDL-C levels; these are significant in some, but not all, studies. Studies in individuals without DM have demonstrated that combined therapy with ezetimibe and a statin produces greater reductions in LDL-C and TG levels, and greater increases in HDL-C, than either therapy alone [99,100]. Several studies have specifically examined the effects of ezetimibe when added to statin therapy in individuals with the MetS and/or T2DM; the results were similar to those observed in groups without DM. Ezetimibe has not been demonstrated to reduce atherosclerosis in combination with a statin. More recently, in the Study of Heart and Renal Protection (SHARP) trial,

Key points

- Type 2 diabetes mellitus (T2DM) involves perturbations in fuel metabolism beyond blood sugar. A classic example is the elevation in ketone body production that can progress to ketosis, indicative of abnormal mobilization and increased catabolism of free fatty acids. Modern approaches to detect, catalog, and interpret comprehensive suites of metabolites in blood or other biofluids (metabolomics) have highlighted that metabolic dysregulation also extends to amino acids and numerous other metabolic pathways.

- It is estimated that the human blood metabolome is composed of >6400 metabolites, and many routinely-detected molecules await final chemical annotation. A number of these non-annotated metabolites are altered by T2DM and track blood sugar control indices, suggesting that future advances in analytical chemistry and chemo-informatics will identify new markers of diabetes, prediabetes, and insulin resistance pathophenotypes and disease severity.

- Blood and tissue metabolite profiling supports the idea that in the T2DM and the insulin resistant states, there is a mismatch between fatty acid fuel delivery and combustion, for example in skeletal muscle. This leads to accumulation of lipid metabolites (diacylglycerol, ceramides, acylcarnitines) that may contribute to "lipotoxicity," hypothesized to promote cell stress, inflammation, and insulin resistance.

- In addition to identifying biochemical pathways altered by T2DM, metabolomics analysis of blood and urine has helped identify predictive metabolite risk markers for T2DM. These markers may prove useful in establishing clinically viable diagnostic panels to predict disease stage or to help direct preventive strategies to thwart disease onset.

- Gut bacteria are implicated in regulating host metabolic health and themselves can be altered by host physiologic status and diet. Thus, considerations related to the human blood metabolome and its associations with metabolic disease should take into account the fact that some metabolites are derived from the gut microbiota. Additional research is needed to understand which, if any, of these "xeno-metabolites" are relevant to T2DM pathophysiology.

Introduction

Type 2 diabetes mellitus (T2DM) is not simply a disorder of blood sugar control, but a condition in which multiple biochemical pathways are impacted. An illustrative example of this is the elevated blood ketone body concentration typical of T2DM, which can progress to diabetic ketoacidosis if insulin action and/or availability deteriorates. The elevations of ketone bodies and the acetone accumulation (with associated "sweet breath odor") of severe or poorly controlled diabetes are indicative of abnormal fatty acid homeostasis and specifically, high lipolysis and hepatic β-oxidation. These observations form the basis for the perspective that a primary event on the path to T2DM development is an aberration in lipid metabolism, that is, chronic exposure of peripheral tissues, liver and pancreatic β cells to high free fatty acids. According to this view, excess free fatty acids promote tissue insulin resistance, increase hepatic glucose output and act in pancreatic β cells to trigger hyperinsulinemia in response to insulin secretagogues [1,2]. While links between altered fatty acids and T2DM-relevant metabolic phenotypes have become well accepted, the mechanisms underlying the associations remain controversial, and a great deal is yet to be learned about other pathways and fuels that contribute to or are impacted by insulin resistance and diabetes. Broad-based metabolite profiling of blood and urine using targeted and untargeted analytical platforms can be a valuable approach in this regard.

By assessing how hundreds of individual metabolites are altered in human and animal models of T2DM, prediabetes, or insulin resistance, it has become evident that these conditions are often associated with alterations in fasting blood or tissue amino acids and their derivatives, systemic bile acids, blood phospholipids, and many as-yet non-annotated "unknown" metabolites. More research is needed to determine which of

these metabolite factors drive disease development and progression, and which are changed in response to deterioration of metabolic homeostasis. This is important not just from the standpoint of understanding basic pathophysiology and symptom etiologies in T2DM, but also to consider if select metabolites or combinations of metabolites have prognostic utility in terms of diabetes risk or disease staging. For instance, despite the clinical utility and cost-effectiveness of blood glucose measurement to diagnose T2DM (and more recently to define prediabetes), elevated blood glucose develops quite late in disease development and progression. Metabolomics tools can move the T2DM field beyond "glucocentric" medicine, to identify earlier biomarkers of disease risk, to foster therapeutic strategies targeting novel metabolic pathways, and ultimately to thwart diabetes or limit its progression and severity. For more comprehensive analysis of "omics" applications to insulin resistance and diabetes, the interested reader is referred to several recent reviews [3–5].

What is "metabolomics?"

Metabolomics is an emerging field of analytical chemistry whose goal is to quantify all metabolites in a biologic sample, typically through application of multiple analytical platforms that enable determinations across a variety of metabolite classes (Figure 18.1). As with other omics-based technologies,

this comprehensive coverage of metabolism has the benefit of allowing the observation of metabolic stressor effects not only at a single target, but also the ripple effect of the stressor, including compensatory responses, across the metabolic landscape. Metabolomics integrates and aggregates the information stemming from genomic, transcriptomic and proteomic events, providing access to a quantitative description of the metabolic phenotype of an individual (Figure 18.2). Moreover, while the genetic code and protein machineries responsible for metabolism provide the distinguishing characteristics between genera, species, and even individuals, the metabolites modified by this elegant and elaborate machinery are far less variable across disparate organisms. For example, all mammals use the same basic suite of metabolites to store, transport and generate energy, build membranes, and use in purine or pyrimidine turnover. Therefore, metabolomics provides a unique and powerful hypothesis-testing and hypothesis-generating tool in both the pre-clinical and clinical research environments.

The ability to discriminate individuals based on pattern of metabolites measured in biofluids has a long history, which has advanced along with technology [6]. An early biomedical application of this concept is newborn screening for inborn errors of metabolism. These tests employ diagnostic profiling of metabolites in blood spots (e.g. acylcarnitines, amino acids, organic acids) that can reveal tissue accumulation of intermediates resulting from specific metabolic lesions [7,8]. Metabolomics developed as an expansion of metabolic profiling, using pattern

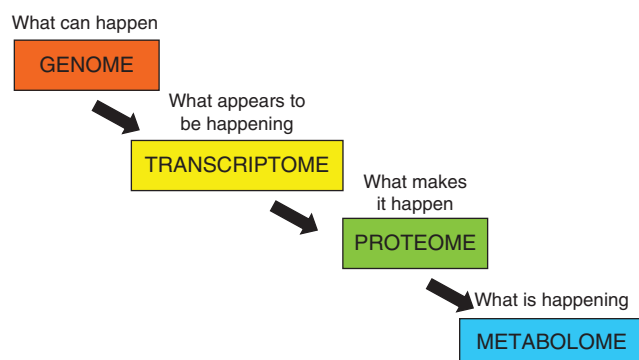
Figure 18.1 Metabolic subdomains of the mammalian metabolome. Analytical protocols using chromatography-coupled mass spectrometry (LC-MS or GC-MS) or proton nuclear magnetic resonance (NMR) are used to simultaneously determine concentrations of metabolites from many metabolic subdomains in urine, blood, or other biofluids. Metabolomics platforms can be either targeted (specific to a metabolite class) or untargeted (more global evaluation of multiple classes in parallel). Source: Kanehisa M, Goto S, Sato Y, Kawashima M, Furumichi M, Tanabe M: Data, information, knowledge and principle: back to metabolism in KEGG. *Nucleic Acids Research* 2014;**42**:D199–D205; Kanehisa M, Goto S: KEGG: Kyoto Encyclopedia of Genes and Genomes. *Nucleic Acids Research* 2000;**28**:27–30. (For a color version of this figure, please see the color plate section.)


Figure 18.2 The metabolome reflects the aggregate outcome of gene-to-whole body events. Determination of the comprehensive metabolite profile can provide insights into upstream enzyme activities and metabolic processes, each of which can be influenced by gene/protein expression levels and sequence polymorphisms. The metabolome is also influenced by the cellular environmental/biochemical milieu, metabolite degradation and excretion (not shown).

recognition to segregate subjects using both identified and unidentified components. However, the field is experiencing a transformation to a quantitative science as analyte peak identification and quantitative efficiency increases. As these efforts continue, repositories and searchable databases like those established within the Human Metabolome Database (www.hmdb.ca/) for metabolite reference ranges in the contexts of health and specific illnesses, will expand [10]. The blood and urine metabolome contains a broad array of metabolites, many of which are dynamically linked to concentrations in tissues and thus report on peripheral tissue metabolism. While less common, metabolomic studies of cereobrospinal fluid have also proven useful, offering novel insights into the progression of diseases such as amytrophic lateral sclerosis [9]. Currently, the human metabolome is believed to contain at least 6400 unique chemical entities. While this number is impressive, many analytes observed in routine metabolomic screens remain unidentified (non-annotated). In the metabolomic paradigm, "unknowns" are considered useful and are assigned unique identifiers allowing their discrete identification in future studies. If such an unknown is later found to associate with a specific disease or treatment intervention, the effort to elucidate its structure may be warranted.

Mass spectrometry and proton nuclear magnetic resonance (NMR) spectroscopy are complementary techniques most routinely employed for metabolomic analyses, often using blood plasma or urine. While NMR is nondestructive, rapid, and inherently quantitative, it is also insensitive and as such best suited for higher-abundance compounds. On the other hand, while mass spectrometric methods are inherently more sensitive and able to discriminate complex mixtures by employing chromatographic separations, true quantification requires access to authentic standards. As with all information-rich technologies, the exploration, analysis and interpretation of metabolomics data is challenging. However, routine statistical approaches exist to effectively manage these data sets and distill them into discrete pieces of information. Metabolomics results are inherently data-heavy and complex, and to properly investigate them requires familiarity with multivariate statistical analyses approaches [11]. For instance, in case-control studies partial least squares discriminate analyses (PLS-DA) is often the default analysis approach. This process filters the data set to find those input variables that best characterize the differences between conditions (e.g. between case and control; pre- and post-treatment). While this approach to data reduction can remove 60–80% of the collected data to focus on variables that most robustly discriminate comparator groups, it can still leave hundreds of metabolites to consider. However, many of these compounds correlate strongly, and understanding which compounds move together (either increasing, or decreasing in concert) can further assemble the data into nodes of information that are descriptive of a biologic process. Hierarchical cluster analyses are the simplest approach to filtering data in this manner, and can parse the body of data into 5–10 pieces of discrete analyte groupings, a manageable amount to aid biologic interpretation. Another important issue that arises when dealing with such large data sets is the multiple comparison problem. Namely, using the statistical convention of a 95% confidence interval; if 100 measurements are made, 5 of these are expected to be statistically different by chance (i.e., $\alpha = 0.05$). Various approaches have been employed to control for this "multiple comparison error." The simplest and most conservative of these is the Bonferonni correction which limits the odds that a given observation is by chance by setting the p-value for significance at α/n. Therefore, if 1000 metabolites are measured and tested for significance, a $p = 0.0005$ would be required to claim a significant difference. A less conservative approach is controlling for the false discovery rate (e.g. [12]), which constrains the likelihood of making a false positive interpretation. However, an underlying assumption in these corrections is that the measured variables are independent and not collinear. In the case of metabolism, many metabolites are inherently linked. Thus, rather than a penalty, repeated determination of a difference in a group of related compounds should enhance interpretations as to the veracity of the results. In practice, this means that users of such data must carefully determine the true number of "independent" measurements that exist in a multivariate data set before application of these p-value adjustments.

Beyond the statistical analysis, visualization of these complex data sets is also an important tool for their analysis and interpretation. Where metabolic networks exist, fluxes and flows along metabolic pathways can be mapped. Similarly, correlation networks can be established showing interconnections between discrete pieces of information, thus helping to bridge and thus integrate the information into a more complete picture.

Altered metabolites and their potential origins in type 2 diabetes and insulin resistance

In recent years, a large number of cross-sectional and prospective studies have revealed specific metabolites and pathways that are altered by, or predictive of, T2DM and insulin resistance. Human insulin resistance, T2DM, and prediabetes involve significant perturbations in multiple metabolic systems, as reflected in positive associations with blood long- and medium-chain acylcarnitines, branched-chain amino acids (BCAAs) or their derivatives, methionine/threonine-derived 2-hydroxybutyrate (2-HB), phenylalanine or tyrosine, and negative associations with blood glycine and select phospholipids [13–27]. These metabolites reflect underlying processes that are impacted by or participate in T2DM or insulin resistance pathophysiology. Based on current knowledge, however, it is unclear which, if any, of the metabolites themselves contribute as a root cause of disease.

As noted above, a perturbation in fatty acid metabolism is a hallmark of insulin resistance and T2DM. The weight of evidence from metabolomics studies and tissue biochemical determinations points to a mismatch of fatty acid fuel delivery (due to elevated lipolysis and circulating fatty acids) relative to complete combustion in mitochondria *in situ* [28]. This leads to accumulation of muscle and blood long- and medium-chain fatty acylcarnitine metabolites that report on tissue fatty acyl-CoA status [14,28]. The tissue origins of higher systemic blood acylcarnitines in T2DM remain to be confirmed, but muscle is a known site of robust acylcarnitine generation. However, mitochondrial mismatch and the incomplete oxidative catabolism of fatty acids likely occurs in all tissues including liver, supported by consistent observations of higher blood ketone bodies in T2DM. Other metabolite derivatives that result from excess tissue fatty acid availability and that have been proposed to be associated with insulin resistance phenotypes include ceramides and diacylglycerols [29].

Both targeted metabolic profiling and global metabolomics experiments have indicated that amino acids should be considered alongside glucose and lipids in the context of the dysmetabolic insulin resistant or T2DM states. In the late 1960s it was observed that BCAAs are increased in the blood of obese, insulin-resistant subjects [30], but only recently did comprehensive metabolite profiling place BCAAs into the spotlight as metabolites associated with insulin resistance [31]. Other essential amino acids such as phenylalanine, tyrosine, methionine and/or the methionine derivatives cysteine-cystine and 2-HB have also been reported to be modestly increased in blood from T2DM and/or insulin resistance conditions (reviewed in [32]). In the case of associations of elevated blood amino acids with insulin resistance and T2DM phenotypes, a growing body of evidence suggests that reductions in tissue utilization and/or incomplete oxidation (due to lower enzyme activities) could play a role. For instance, insulin resistance in a human cohort

(highest insulin concentration) was associated with significantly attenuated post-oral glucose tolerance test (OGTT) reductions in blood leucine/isoleucine [33], supporting the idea that lower insulin-stimulated tissue BCAA utilization occurs with insulin resistance. Lower expression of mitochondrial branched chain ketoacid dehydrogenase complex (BCKDC, main control point of BCAA oxidative catabolism) and associated proteins and genes is evident in visceral white adipose tissue from obese, insulin-resistant rodents and humans [34,35] (and references therein). Reduced expression of BCKDC, and lower enzyme activity due to the high fatty acid environment of T2DM and insulin resistance, could promote increased concentration of upstream metabolites such as BCAAs, methionine/cysteine, and 2-HB/2-ketobutyrate [32]. Recently, metabolomics analysis of blood from a large prospective study cohort (Framingham Heart Study) revealed the lysine derivative 2-aminoadipic acid (2-AAA) as predictive of T2DM development [36], with persons in the highest quartile of 2-AAA concentrations at fourfold greater risk. Lower blood glycine concentrations have also been reported to associate with insulin resistance or T2DM risk (e.g. [19,20,24,25]). The origins of the latter metabolic phenotypes remain unknown.

Additional metabolite classes that are coming to the fore in terms of their potential association with insulin resistance or T2DM risk include bile acids and choline-containing phospholipids. For instance, insulin-resistant individuals had a blunted increase in blood glycochenodeoxycholic acid following OGTT [33]; yet, fasting concentration of this metabolite was increased in a cohort of impaired glucose tolerant vs. normal glucose tolerant individuals [18]. Phosphatidylcholine derivatives including glycerophosphatidylcholine metabolites are consistently reported to be reduced in T2DM or insulin resistance [16,18,20,25,37]. Further research is needed to determine why insulin resistance and T2DM phenotypes associate with blood patterns of bile acids and phospholipids, but it is possible that changes to the gut environment and/or gut bacteria (microbiota) play a role. Recent metabolomics results highlight that the host's metabolic health and insulin resistance status are associated with differences in profiles of blood and urine xeno-metabolites ("nonself" metabolites) (e.g. [18,38]). Interestingly, taxonomic diversity in the gut microbiome is significantly different in persons displaying risk markers for cardiometabolic disease including insulin resistance [39], and there are clear differences in gut microbe communities when comparing subjects with normal glucose tolerance, prediabetes, and T2DM [40–43].

Future directions and potential application of metabolite profiling in type 2 diabetes

Metabolomics approaches have unmasked a variety of metabolic pathways influenced by T2DM or insulin resistance, moving the field of metabolic physiology beyond a "glucocentric" viewpoint of these conditions. However, a difficulty in interpretation is

that the fasting concentration of a metabolite only reflects a single moment in time, and etiology or tissue origins of any metabolite differences across comparator groups requires further validation. To fully elaborate the molecular and physiologic mechanisms underlying metabolite differences, future efforts will conduct systematic exploration into relevant enzymology, biochemistry, and flux measures (i.e., metabolite turnover, anabolism-catabolism events). Furthermore, efforts are underway to determine which systemic metabolites associated with metabolic diseases such as T2DM emanate from gut microbes or co-metabolism of microbe and host.

From the standpoint of clinical practice, what does metabolomics have to offer? In the future, determination of metabolic variants in drug metabolism in the clinic could be used to tailor therapeutic regimens, revolutionizing the application of "pharmacometabolomics" to individualized medicine [44]. If applied as a tool to routinely characterize patient health, metabolomics should provide novel diagnostic and prognostic tools allowing early disease identification and intervention. While fasting samples should prove valuable in this regard, it is likely that dynamic changes in one or more analytes following OGTT or other challenges will prove even more sensitive. Comprehensive metabolite profiling of blood and tissues has already led to at least one first-generation analyte panel relevant to T2DM and metabolic disease research and medical evaluation. For instance, Quantose™ is a fasting blood analyte panel available for research purposes from Metabolon (Research Triangle Park, North Carolina, USA), and includes the analytes 2-HB, 1-lineoyl-glycerophosphocholine (L-GPC), oleic acid, and insulin. The panel score reflects relative risk for T2DM and may be useful for experiments involving relative stage or severity of disease progression, or those examining efficacy of interventions. The same panel is also incorporated into a Diabetes Prevention and Management Panel offered by Health Diagnostic Laboratory (Richmond, Virginia, USA). These early examples of tests that are based on multi-analyte platforms have their foundation in pioneering cross-sectional and prospective cohort metabolomics research. With advancements in technology and clinical uptake, it is feasible that robust predictive tests for T2DM will become commonplace, helping guide prevention strategies well before disease onset, and treatment strategies to minimize disease severity.

NAFLD, NASH and non-traditional associations with diabetes

Pathogenesis of nonalcoholic fatty liver disease (NAFLD)

Hannele Yki-Järvinen

Department of Medicine, University of Helsinki, Minerva Foundation Institute for Medical Research, Helsinki, Finland

Key points

- Nonalcoholic fatty liver disease (NAFLD) is the most common liver disorder.
- NAFLD covers a range from simple steatosis (NAFL) to nonalcoholic steatohepatitis (NASH).
- NASH may progress to cirrhosis and end-stage liver disease.
- NAFLD is the most common cause of hepatocellular carcinoma (HCC).
- NAFLD predicts type 2 diabetes and cardiovascular disease independent of obesity.
- Obesity and increased simple sugar intake are the major acquired risk factors for NAFLD.
- The fatty liver due to NAFLD is insulin resistant and overproduces glucose and VLDL, which results in hyperinsulinemia and low HDL cholesterol.
- Carriers of the I148M variant in PNPLA3 (PNPLA3 NAFLD) have an increased risk of NASH and HCC but do not have features of the "metabolic syndrome" (MetS).

Introduction

NAFLD is defined as steatosis (>5–10% of hepatocytes are fatty), which is not due to excess use of alcohol (defined in European and American guidelines as >20 g of alcohol daily for women and >30 g for men), or other conditions as determined by careful family and medical history, and laboratory tests to exclude at least steatosis due to viral and autoimmune causes and iron overload [1].

NAFLD is usually asymptomatic and most patients have normal transaminases (ALT $<30–40\,U\,L^{-1}$ for men and $<20–30\,U\,L^{-1}$ for women) [2,3], although NAFLD is the commonest cause of incidentally discovered elevated liver function tests [4] and the most common cause of chronic liver disease [5] (Figure 19.1). The prevalence of NAFLD depends on the method of diagnosis but is as common as the MetS (metabolic syndrome). The estimated worldwide prevalence is in the range from 15% (China) to 30% (Dallas Heart Study) [6].

Some patients with NAFLD have NASH, which is characterized in addition to steatosis by ballooning necrosis in the vicinity of steatotic hepatocytes, mild inflammation, and possibly fibrosis [7]. NASH can only be diagnosed by a liver biopsy. Recent reviews have estimated the worldwide prevalence of NASH to be 3–6% [6,8]. Although the main cause of excess mortality in NASH is CVD [8], NASH may progress to cirrhosis and end-stage liver disease. Cirrhosis may occur in ∼5% of patients with NASH (see [8] for review) (Figure 19.2). NASH is perhaps the most common cause of cryptogenic cirrhosis [9]. It is currently the third most important indication for liver transplantation in the US and the only cause with an increasing incidence [10]. Recent data have shown that NAFLD is the most prevalent cause of HCC [11] (Figure 19.1), which may occur even without cirrhosis in patients with NAFLD [12,13]. The risk of HCC is increased at least twofold in obesity and type 2 diabetes [13] and may be especially high in patients with NAFLD, who are carriers of the common variant in PNPLA3 (see later) [14]. Identification of patients at risk for NASH and HCC is a major challenge.

The liver is the site of production of two of the key components of the MetS, fasting serum glucose and very-low density lipoprotein (VLDL), which contains most of the triglycerides present in serum. In subjects with NAFLD, the ability of insulin to normally suppress production of glucose and VLDL is impaired resulting in mild hyperglycemia and hypertriglyceridemia, two key features of the MetS [15,16]. The liver, once fatty, also overproduces other markers of cardiovascular risk such as C-reactive protein (CRP), fibrinogen, and coagulation factors [8,17]. The ensuing chapter is focused on reviewing the pathogenesis of NAFLD mostly based on human studies.

Pathogenesis of NAFLD

Sources of intrahepatocellular triglycerides

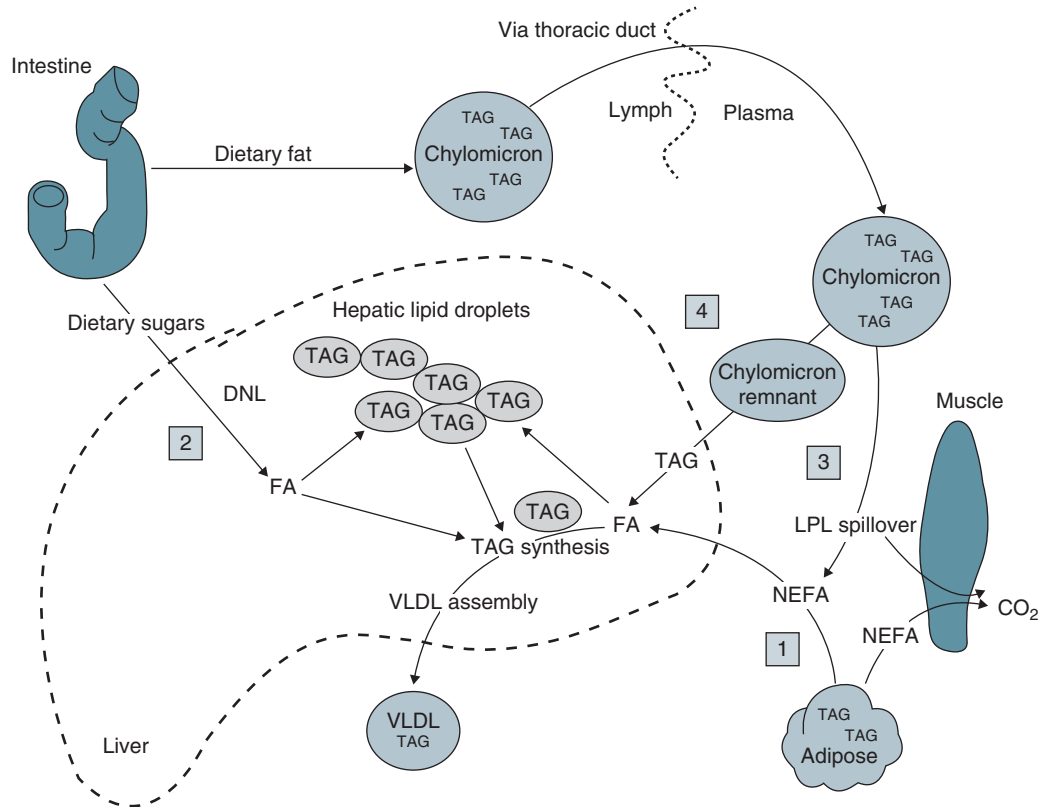
The hallmark of NAFLD is steatosis, that is, accumulation of triglycerides within hepatocytes. The fatty acids in these triglycerides can be derived from peripheral lipolysis, that is, fatty acids released from adipose tissue, *de novo* synthesis of fatty acids from simple sugars such as glucose and fructose as well as from amino acids via the pathway of *de novo* lipogenesis (DNL), or from dietary fatty acids, which can reach the liver via the spillover pathway and through uptake of intestinally derived chylomicron remnants [18] (Figure 19.3). Spillover is defined as the amount of free fatty acids (FFA) that are released from triglycerides during intravascular lipolysis but not taken up by adipose or muscle tissues. Studies using stable isotopes in humans have suggested that after an overnight fast and during the night, lipolysis provides approximately half of the fatty acids stored in intrahepatocellular triglycerides [19]. The contribution of lipoplysis to intrahepatocellular triglycerides does not appear to be increased if weight-matched subjects with and without
Figure 19.2 NAFLD as a predictor of disease. Once fatty due to nonalcoholic causes, often in subjects with the metabolic syndrome (MetS), the liver is insulin resistant and overproduces many factors such as glucose, very-low density lipoprotein (VLDL), C-reactive protein (CRP), plasminogen activator inhibitor 1 (PAI-1), fibrinogen, coagulation factors (FVIII, XI, XII) and cholesterol. In some subjects, perhaps 5%, nonalcoholic steatohepatitis (NASH) develops. NASH predisposes to cirrhosis and hepatocellualr carcinoma. Obesity, type 2 diabetes and insulin resistance as well as the I148M allele in PNPLA3 are predictors of NASH. NAFLD also increases, independent of obesity, the risk of cardiovascular disease, deep venous thromboembolism, and cholesterol gallstones.


Figure 19.3 Sources of intrahepatocellular triglycerides (TAGs) in NAFLD. Dietary fat is transported from the gut in chylomicrons in lymph via the thoracic duct to the circulation. Chylomicrons undergo intravascular lipolysis (1) during which part of the FFA are released by lipoprotein lipase (LPL) at the capillary endothelium and are taken up by adipose and muscle tissues. During this process, some of the FFA spill over to the systemic circulation where they are available for uptake by tissues such as the liver (3). After intravascular lipolysis, chylomicron remnants are taken up by the liver (4). Fatty acids (FA) can also be synthesized from dietary sugars and amino acids via the *de novo* lipogenesis (DNL) pathway (2). In the liver, part of the TAGs are routed for VLDL assembly. Lipolysis of TAG to FA may occur prior to TAG synthesis for VLDL. Source: Donnelly 2005 [18]. Reproduced with permission of American Society for Clinical Investigation.

increased liver fat content due to NAFLD are compared [19]. Despite this, multiple studies have shown adipose tissue lipolysis to be increased in subjects with NAFLD [20,21]. The pathway, which seems most abnormal in NAFLD is DNL [19]. During a meal, the contribution of lipolysis decreases while that of dietary fatty acids increases [18]. Another mechanism by which triglycerides can accumulate is defective lipolysis within hepatocytes. A major form of NAFLD due to genetic variation in PNPLA3 has recently been identified. The I148M variant in PNPLA3 may impede breakdown of intrahepatocellular triglycerides. This cause of NAFLD as well as others and the mechanisms by which they contribute to NAFLD are discussed later.

Cause of NAFLD: obesity and abnormalities in adipose tissue

Although both NAFLD and the MetS can occur in nonobese subjects, the prevalence of NAFLD is markedly increased in obesity as is that of the MetS. In the third National Health and Nutrition Examination Survey (NHANES), the prevalence of NAFLD averaged 7.5% and 6.7% in normal-weight men and women but was 57 and 44% in persons with a body mass index (BMI) $> 35\,\text{kg}\,\text{m}^{-2}$ [22]. Asians have a higher prevalence of NAFLD than Caucasians for a given BMI. For example, the mean BMI in 6905 Chinese adults with ultrasound-diagnosed NAFLD was $23.6\,\text{kg}\,\text{m}^{-2}$ as compared to $21.5\,\text{kg}\,\text{m}^{-2}$ in those without NAFLD [23]. Obesity is a true cause of NAFLD and hepatic insulin resistance as weight loss rapidly reverses both (see [24] for review). Bariatric surgery induced remission regresses histologic changes, at least steatosis and ballooning, in NASH [25].

In obese subjects, who have NAFLD, adipose tissue is characterized by multiple alterations such as hypoxia (see [26] for review), increased infiltration of macrophages surrounding dead adipocytes and expression of chemokines and pro-inflammatory cytokines [27], fibrosis as well as deficiency of adiponectin [28]. Inflamed adipose tissue is insulin resistant leading to increased FFA flux to the liver especially under conditions mimicking the postprandial state [29]. In obese subjects, a decrease in serum adiponectin is likely to contribute to fat accumulation in the liver and may also induce hepatic inflammation and insulin resistance (see [28] for review). Changes in gut microbiota have been suggested to contribute to the pathogenesis of both obesity and NAFLD syndrome (see [30] for review). The change in intestinal bacterial flora is thought to alter the permeability of gut mucosa to inducers of inflammation such as endotoxin. In addition to abnormal adipose tissue metabolism, an increase in simple sugar intake and DNL characterizes obese a compared to nonobese subjects (see later).

Over 50 years ago, Jean Vague classified obese subjects according to the degree of "masculine differentiation" [31] into those with "gynoid" and those with "android" obesity. Gynoid obesity was characterized by lower-body deposition of fat (around the thighs and buttocks, "pear-shaped") and relative underdevelopment of the musculature, while android obesity defined upper-body (truncal, "apple-type") adiposity, greater overall muscular development and a tendency to develop hypertension, diabetes, atherosclerosis, and gout. These phenotypic observations have subsequently been confirmed in many cross-sectional and prospective studies (see [32] for review). The amount of visceral fat correlates closely with the amount of fat in the liver [3].

Although abdominal obesity is a marker of NAFLD and the MetS, it is controversial whether visceral fat is "causal or correlative" [33] or "the major culprit or an innocent bystander" [34] for features of the MetS or NAFLD. The small visceral depot has been suggested to be harmful because omental and mesenteric adipocytes have a higher rate of lipolysis than subcutaneous ones, and this could liberate excessive amounts of FFA into the portal vein and make the liver fatty. Visceral fat may also release more inflammatory cytokines than subcutaneous adipose tissue [32].

However, this "portal theory" can be questioned [33]. When groups of subjects, who have similar amounts of liver fat but differ with respect to the amount of subcutaneous and visceral fat, are compared, there are no defects in insulin suppression of lipolysis or in rates of VLDL production [35]. If overactive lipolysis were responsible for the harmful effects of visceral fat, one would predict this depot to be reduced rather than enlarged. Surgical removal of omental fat in humans does not improve hepatic insulin sensitivity [36].

Patients with NAFLD frequently have obstructive sleep apnea (OSA). According to two meta-analyses pooling data from 18 [37] and 11 [38] studies, patients with OSA have a significantly and 2.0–2.6-fold increased risk of having NAFLD and a significantly higher risk of liver fibrosis independent of obesity [39]. This increased risk could be mediated by hypoxia (see [26] for review). Patients with the polycystic ovary syndrome are more insulin resistant and have a higher liver fat content than equally obese subjects without the syndrome [40].

Cause of NAFLD: high simple sugar intake and *de novo* lipogenesis

The increase in the consumption of foods containing high amounts of added simple sugars such as soft-drinks, deserts, cookies, sugar and candy, and fruit drinks has far exceeded that in intake of any other food group [41]. Recent prospective epidemiologic data have shown that an increase in the intake of sugar-sweetened beverages (SSB) predicts both obesity, type 2 diabetes, CVD, and NASH independent of other factors such as energy intake. In the HPFU (Health Professionals Follow-Up Study), the risk of CVD was significantly increased in men using high amounts of SSB after adjusting for confounders such as physical activity and energy intake. Intake of SSB was also significantly associated with features of the MetS such as hypertriglyceridemia, low HDL cholesterol, and high CRP and IL-6 concentrations [41]. There were similar findings in the Nurses' Health Study. Analysis of food questionnaires from 427 adults with biopsy-proven NASH found fructose consumption, after adjusting for age, gender, BMI and total caloric intake, to be significantly associated with fibrosis [42]. Taken together

these data suggest that simple sugars significantly contribute to the epidemics of obesity, type 2 diabetes, CVD, and NASH.

Simple sugars are converted to fat in the liver via DNL [43]. This pathway accounts for some 5% of liver fat synthesis in normal subjects but is threefold higher in patients with NAFLD when compared to equally obese subjects without an increased liver fat content [19]. It produces exclusively saturated fatty acids [43], which relative proportion in the liver [44], as well as rate of production increases in direct proportion to liver fat in humans [45]. Saturated fats produced by DNL as compared to fatty acids derived from the diet may cause more lipotoxic injury (see [46] for review). Some of fructose may be metabolized in the colon and influence gut microbiome [46]. Overfeeding a high carbohydrate (1000 extra simple sugar calories as candies and sugar-sweetened beverages/day) diet for merely 3 weeks increases DNL, liver fat (by 30%), and serum triglycerides and lowers HDL cholesterol [47]. Meta-analyses comparing isocaloric substitution of carbohydrate by fat (saturated or monounsaturated or polyunsaturated) have shown that high carbohydrate but not high fat diets produce the dyslipidemia typical of the MetS and NAFLD [48]. The rate of DNL is increased in obese subjects who are hyperinsulinemic but not in those who are normoinsulinemic, even when obese subjects are consuming the same diet as nonobese subjects [49]. These data imply that excessive intake of simple sugars recapitulates key features of the MetS as well as NAFLD, and that DNL is also increased in hyperinsulinemic subjects irrespective of diet composition.

Cause of NAFLD: physical inactivity

Although physical training predominantly enhances muscle insulin sensitivity, cross-sectional epidemiologic data and studies on effects of physical training suggest that exercise may decrease liver fat even in the face of unchanged body weight [50]. In a cross-sectional study in 72,359 healthy Korean adults, subjects who were exercising regularly had a 28–53% lower risk of NAFLD across almost all BMI deciles [51]. In a small ($n=12$) but carefully performed mechanistic study, exercising 30–60 min five times a week for 16 weeks modestly decreased liver fat by 10% in the absence of changes in body weight [52]. The effect of exercise seems small in comparison to the effects of a hypocaloric ketogenic diet; when the same group followed a low carbohydrate diet, liver fat was shown to decrease by 30% within 48 hours [53]. Exercise may reduce liver fat by channeling dietary carbohydrates to muscle glycogen away from DNL [54].

Causes of NAFLD: familial and genetic factors
Family history, ethnicity

NAFLD has been reported to run in families with heritability estimates of around 40% [55]. This familial clustering is observed even after adjusting for age, gender, and obesity [55]. The heritability of S-ALT due to nonalcoholic causes based on a study in twins was 55% [56]. Ethnicity influences the prevalence of

NAFLD [57]. In the Dallas Heart Study, 45% of Hispanics, 33% of Whites, and 24% of Blacks had NAFLD [2]. These differences were only in part attributable to differences in BMI. As discussed later, genetic variation in PNPLA3 may contribute to ethnic variation in the prevalence of NAFLD.

Age and gender
In the third NHANES, the prevalence of NAFLD increased linearly from subjects less than 30 years to those aged 50–60 years and was higher in men than in women.

The PNPLA3 I148M variant
A common genetic variant, an allele in PNPLA3 (rs738409[G], encoding I148M) has been found to be a major factor in determining liver fat content and susceptibility to NASH, independent of obesity. This variant was discovered in 2008 in a genome-wide association scan in Hispanic, African American, and European American individuals. It showed genetic variation in PNPLA3 to confer susceptibility to NAFLD. An allele in PNPLA3 (rs738409[G], encoding I148M) was associated with increased liver fat and also hepatic inflammation and fibrosis [58]. This finding has subsequently been reproduced. In a meta-analysis comprised of 16 studies published in 2011, homozygous carriers of the variant as compared to noncarriers had a 73% higher lipid fat content, a 3.2-fold greater risk of high necro-inflammatory scores and a 3.2-fold greater risk of developing fibrosis [59] (Figure 19.2). The association between the PNPLA3 variant allele and steatosis has been observed in seven out of eight GWAS studies and in multiple other studies including Chinese, African Americans, participants of the third NHANES, children with NAFLD, and morbidly obese patients [60]. The association between the PNPLA3 rs738409[G] allele and severity of histologic liver disease has also been confirmed [60]. As summarized in a meta-analysis, recent studies have also shown that the PNPLA3 rs738409[G] allele is associated with an increased risk of HCC [14]. In the population-based Dallas Heart Study, the prevalence of the PNPLA3 rs738409[G] allele displayed ethnic variation, being highest in Hispanics and lowest in African Americans [58]. The PNPLA I148M variant is indeed common. In subjects with NAFLD diagnosed by US or ^{1}H-MRS, the prevalence of subjects homozygous vs. heterozygous for the rs738409[G] allele has averaged 12 vs. 39% in Europeans [61], 17 vs. 50% in Chinese [62], and 19 vs. 51% in Taiwanese children [63]. In subjects without NAFLD, the prevalences were 8 vs. 31%, 11 vs. 47%, and 12 vs. 48%, respectively.

In humans, PNPLA3 is expressed predominantly in the liver. Initial *in vitro* studies using purified human PNPLA3 showed that the wild-type enzyme hydrolyzes triglycerides and that the I148M substitution abolishes this activity [64]. These data suggest that the I148M substitution is a loss-of-function mutation impairing triglyceride hydrolysis. However, PNPLA3 also stimulates lipogenesis *in vitro* and the PNPLA3^{I148M} variant was suggested to increase this activity [65]. Thus, there are still

uncertainties as to how the gene variant influences the biology of human NAFLD.

In almost all studies, the NAFLD associated with PNPLA3$^{148MM/148MI}$ was not accompanied by either insulin resistance, hyperglycemia, hypertriglyceridemia, or a low HDL cholesterol concentration, or with inflammation in adipose tissue [66]. On the other hand, it is important to recognize that the same person may have NAFLD due to obesity/insulin resistance and NAFLD due to the PNPLA3 I148M gene variant. Genotyping for PNPLA3 at rs738049 may become part of screening strategies in the clinic for patients with steatosis as this may help in predicting risk of NASH and HCC.

Consequences of NAFLD

Hyperglycemia and hyperinsulinemia

After an overnight fast, the main action of insulin is to restrain endogenous hepatic glucose production, while the rate of glucose uptake is largely insulin-independent [67]. In subjects with NAFLD [15,21] the ability of insulin to inhibit glucose production is impaired resulting in mild hyperglycemia. The latter stimulates insulin secretion leading to hyperinsulinemia. Fasting hyperglycemia and hyperinsulinemia are thus consequences of hepatic insulin resistance and correlate positively with liver fat, even independent of BMI (Figure 19.4).

Nondiabetic hyperglycemia and hyperinsulinemia are well established predictors of type 2 diabetes. Consistent with such data and the close association between liver fat and these predictors, NAFLD diagnosed by US has been shown to predict type 2 diabetes in multiple prospective studies (see [8] for review). The association between NAFLD and type 2 diabetes was independent of obesity in all studies, which adjusted for obesity. NAFLD predisposes to type 2 diabetes by increasing the amount of insulin needed to keep hepatic glucose production in the nondiabetic range. However, in subjects predisposed to develop type 2 diabetes, β cells are unable to sustain insulin secretion leading to relative β cells failure and overt type 2 diabetes
Figure 19.4 Consequences of hepatic insulin resistance. Upper panel: Insulin normally restrains hepatic glucose production. Once fatty, the ability of insulin to inhibit glucose production is impaired, which stimulates insulin secretion leading to hyperinsulinemia. Lower panel: Insulin normally restrains hepatic VLDL production. Once fatty, the ability of insulin to inhibit glucose production is impaired, which stimulates insulin secretion leading to hyperinsulinemia.

(Figure 19.2) [67]. Some studies have suggested that NAFLD predicts type 2 diabetes even independent of all components of the MetS and thus that NAFLD is an even better marker of risk than the MetS.

Hypertriglyceridemia and low HDL cholesterol, increased risk of type 2 diabetes

Under fasting conditions, the liver of subjects with NAFLD overproduces triglyceride-enriched VLDL particles despite hyperinsulinemia when compared to equally obese subjects without NAFLD [68]. Insulin normally decreases production of VLDL by inhibiting adipose tissue lipolysis, and by directly suppressing hepatic production of VLDL [69]. In subjects with NAFLD, insulin fails to suppress both lipolysis [20] and production of triglyceride-rich VLDL particles from the liver [16]. This hepatic overproduction of large triglyceride-rich VLDL particles is another consequence of hepatic insulin resistance and the major contributory mechanism underlying the increase in serum triglycerides in subjects with the MetS and NAFLD [69] (Figure 19.4). The increase in VLDL leads to lowering of HDL cholesterol and also to generation of small dense LDL particles, which are known to be highly atherogenic (see [32] for review).

Markers of cardiovascular risk, increased risk of cardiovascular disease and thromboembolic complications

The liver in subjects with NAFLD overproduces multiple markers of cardiovascular risk. These include, in addition to liver enzymes, glucose, and VLDL, increased production of C-reactive protein (CRP), fibrinogen, coagulation factors (FVII-IX, XI-XII), and plasminogen activator inhibitor-1 (PAI-1), and decreased production of insulin-like growth factor binding protein 1 (IGFBP-1) and sex-hormone binding globulin (SHBG) [70]. Changes in these circulating markers could explain, at least partly why NAFLD predicts CVD (see [8] for review), also when adjusted for obesity [8]. The changes in the markers of fibrinolysis and coagulation could contribute to an increased risk of thromboembolic complications in NAFLD [17].

Other metabolic disease

NAFLD increases the risk of cholesterol gallstones [41]. The fatty liver overproduces cholesterol [71] and displays other alterations in cholesterol metabolism [72], which may contribute to formation of cholesterol gallstones and also hepatic damage (Figure 19.2). NAFLD is also associated with an increased prevalence of obstructive sleep apnea and polycystic ovary syndrome.

Conclusions

NAFLD is a new epidemic, which has important health consequences. The data summarized in this review support the idea that NAFLD, which is not due to genetic variation in PNPLA3 "metabolic NAFLD," closely resembles the MetS with respect to its causes and consequences. For these subjects, liver fat content is an excellent marker of the metabolic abnormalities characterizing the MetS. Indeed, since NAFLD predicts type 2 diabetes, even independent of the MetS, it may be better than the MetS in predicting risk. In the absence of simple and reliable tools to diagnose NAFLD, screening for simple steatosis is not recommended at present [1]. However, an incidental finding of NAFLD should lead to careful evaluation of the presence of risk factors for diabetes and CVD as well as for NASH. NAFLD may also be encountered more often than by chance in patients with otherwise unexplained deep venous thromboembolism and gallstone disease. On the other hand, the possibility of NASH should be remembered in all patients with the MetS by calculating appropriate risk scores such as the NAFLD liver fibrosis score [73,74]. PNPLA3 genotyping may become a routine test in all subjects with NAFLD as these patients are at particularly high risk of NASH and even HCC but not diabetes and CVD. However, the clinical utility of such testing still warrants further evaluation.

Treatment of nonalcoholic fatty liver disease (NAFLD) and nonalcoholic steatohepatitis (NASH)

Fernando Bril, Kwame Ntim, Romina Lomonaco and Kenneth Cusi
University of Florida, Gainesville, FL, USA

Key points

- Nonalcoholic fatty liver disease (NAFLD), and its more severe form with hepatocyte necro-inflammation and eventual lobular fibrosis called nonalcoholic steatohepatitis (NASH), are much more common in clinical practice than previously thought. This is in part due to the increase in obesity and T2DM.
- Lifestyle intervention remains the gold-standard treatment for NAFLD and NASH.
- Although the best lifestyle strategy to address NAFLD/NASH is not currently known, any intervention leading to significant (>5–10%) weight reduction (i.e., diet, exercise, bariatric surgery) decreases liver triglyceride accumulation, improves liver histology and ameliorates the associated comorbidities (dyslipidemia, insulin resistance, hyperglycemia).
- Of the many drugs studied in clinical trials for the treatment of NASH, only vitamin E, obeticholic acid and pioglitazone offer clear evidence of benefit from RCTs in terms of safety and efficacy in adults with NASH.
- New pharmacologic agents are undergoing clinical trial testing and offer promise for the management of patients with NAFLD/NASH.

Introduction

Nonalcoholic fatty liver disease (NAFLD) encompasses a spectrum of liver disease ranging from simple liver fat accumulation to severe hepatic necro-inflammation (nonalcoholic steatohepatitis or NASH), and eventually cirrhosis [1]. Nonalcoholic fatty liver disease has become the most common cause of chronic liver disease and its prevalence will continue to increase as a consequence of the obesity epidemic. According to a study by Szczepaniak et al. [2] using the current gold-standard magnetic resonance imaging and spectroscopy (MRS) technique, about one third of the adult US population and as many as two thirds of obese adults have NAFLD. More importantly, a significant number of patients are believed to have NASH. The real proportion remains uncertain depending on the population studied, clinical setting, and diagnostic screening approach. In patients screened for NAFLD in tertiary medical care settings, the prevalence of liver biopsy-proven NASH among patients with steatosis ranges from 30% to 44% [3,4].

Previously thought to be a harmless condition associated with the metabolic syndrome, NAFLD and NASH are now recognized as important risk factors for cardiovascular disease [5,6], type 2 diabetes mellitus (T2DM) [7], cirrhosis [8], and hepatocellular carcinoma [9]. This emphasizes the importance of early diagnosis. However, the diagnosis of NASH can be challenging as it depends on performing a liver biopsy, which many primary care physicians and patients are unwilling to undergo.

Once NASH is diagnosed in a patient with T2DM, the main issue is how this diagnosis will affect the patient's overall management. At present, there is no drug specifically approved for the treatment of NAFLD or NASH. While some pharmacologic agents appear to be promising [10,11], lifestyle intervention (mainly diet plus exercise) remains the standard of care to avoid disease progression [12,13].

Several drugs have been assessed in clinical trials for the treatment of NASH [10,11,14–19]. However, most of the studies have been small, of short duration, or had relied on surrogate markers (liver enzymes or ultrasound) for the diagnosis of NAFLD and for outcome measures. Only vitamin E (in patients without T2DM) and pioglitazone (in both patients with or without T2DM) have proven to be safe and effective in randomized, placebo-controlled trials [10,11]. Ongoing studies are assessing novel drugs for NAFLD/NASH but clinical use may be a few years away at the present time. Therefore, this chapter focuses primarily on the available evidence of nonpharmacologic and pharmacologic approaches for NAFLD and NASH.

Role of lifestyle intervention in NAFLD

It has been shown that hypocaloric diets, with or without physical activity, reduce the risk of cardiovascular disease (CVD) and T2DM [20,21]. However, their effect in patients with NAFLD has been less well studied. Most studies have had serious shortcomings ranging from small sample size to short duration [22–28], or simply lacking a control group [29–31]. Even in strongly controlled studies, significant variability in the dietary or exercise protocols make comparisons between studies and generalized conclusions difficult [32,33]. Another problem is that in the majority of trials, the diagnosis of NAFLD and treatment effect were not assessed by means of liver histology (liver biopsy), but rather with the use of surrogate markers [34–38]. Beyond these limitations, there appears to be consensus that patients with NAFLD benefit from diet and physical activity [13], although it is still unclear which lifestyle intervention strategy is the most beneficial. Studies have been inconsistent when assessing different types of diet (low fat, low carbohydrates, and so on) [22–24,39,40], and exercise training protocols (i.e., aerobic vs. resistance training) [41], either with or without weight reduction. In the following sections we will discuss efforts in trying to establish the best approach for patients with NAFLD/NASH.

Dietary alone interventions

The effect of dietary intervention alone for the management of NAFLD and NASH has been evaluated extensively over the past 2–3 decades [42,43]. These studies can be divided into two main types: those that have focused on weight reduction only, and clinical trials that have assessed the role of a particular dietary composition on hepatic steatosis.

Several small and uncontrolled studies have examined the effect of diet-induced weight reduction (without physical activity changes) on plasma aminotransferases levels and hepatic steatosis measured by either liver ultrasound [34,44] or computed tomography (CT) [35,36]. Taken together, a 4–5% weight loss by dietary intervention alone usually improves plasma aminotransferases levels and hepatic steatosis. Unfortunately, these surrogate markers of liver disease have been shown to have weak correlations with histologic findings [45], and do not allow to make firm conclusions regarding the long-term value of weight reduction by dietary intervention alone in NAFLD.

Table 20.1 summarizes the studies that have assessed the effect of weight reduction by diet alone on hepatic triglyceride accumulation by MRS in patients with NAFLD. As can be observed, independently of the type of diet used, weight reductions ranging from 6.5 to 11.0% have been associated with a significant reduction in liver fat content by MRS in the order of 38% to 81%. Moreover, Tendler et al. [46] in a provocative small ($n = 5$) pilot study reported that after 6 months of a low-carbohydrate, ketogenic diet, a reduction of ~11% of body weight was associated with qualitative improvements in liver histology.

Only a few studies have examined the role of dietary composition in addition to negative caloric balance. Ryan et al. [47] reported significant decrease in plasma aminotransferase levels with a low-carbohydrate diet when compared to a high-carbohydrate regime in patients with T2DM. However, interpretation is difficult as this improvement was associated with a larger weight reduction in the low-carbohydrate diet group. Kirk et al. [39] found similar reductions in liver fat content and weight after 11 weeks of a low-carbohydrate (high-fat) vs. high-carbohydrate diet. Of interest, short-term assessment after 48 hours of calorie restriction already showed a significant reduction in LFAT (~20%) in the low-carbohydrate diet when compared to the high-carbohydrate arm, even before any meaningful weight change. In 170 overweight and obese patients with NAFLD treated over a 6-month period with a hypocaloric diet restricting either carbohydrates or fat, Haufe et al. [40] concluded that both interventions were equally

Table 20.1 Studies assessing dietary interventions with weight reduction in patients with NAFLD by MRS

Author [ref.] (year)	Type of study	Duration (weeks)	Type of hypocaloric diet	Weight loss	Change in liver fat by MRS
Petersen [30] (2005)	Uncontrolled ($n = 8$)	7	Very-low-fat diet	↓8%	↓81%**
Kirk [39] (2009)	RCT ($n = 22$)	11	Low- vs. high-carbohydrate diet	↓7.6% vs. ↓7.3%	↓38% vs. ↓45%*
Viljanen [29] (2009)	Uncontrolled ($n = 33$)	6	Balanced hypocaloric diet	↓11%	↓60%**
Haufe [40] (2011)	RCT ($n = 102$)	24	Low-fat vs. low-carbohydrate	↓6.5% vs. ↓7.5%	↓42% vs. ↓47%**

effective in reducing weight and excessive hepatic triglyceride accumulation.

Based on the above findings, it may be concluded that the potential impact of dietary composition is less important than the overall weight reduction achieved. Unfortunately, studies have been of short duration (≤6 months) and few have tried to assess the effect of dietary composition alone during weight-stable diets (summarized in Table 20.2). As can be observed in Table 20.2, isocaloric diets that do not affect overall caloric intake and weight have only a minor impact on hepatic steatosis (∼13–20%) [22,23], suggesting that weight loss per se may be the most important factor in ameliorating hepatic steatosis.

Physical activity only

Physical activity has also been suggested to be beneficial in patients with NAFLD and NASH [48]. In a large cohort of 813 patients, 54% of patients with biopsy-proven NAFLD were considered to be physically inactive when screened using a self-reported physical activity questionnaire [49]. Of note, the majority of patients with NAFLD reported that they did not engage at all in any physical activity. Though limited by the nature of the data collection (survey compared to direct observation), the above study suggests that increasing physical activity may play a role in the prevention or treatment of NAFLD.

Results among the many exercise studies in NAFLD are difficult to interpret due to heterogeneity in the type of exercise, baseline fitness levels, and amount of weight loss achieved. Moreover, few offer details about the changes in caloric content or dietary composition during the study. Like with dietary interventions, many of these trials have relied on weak surrogate biomarkers for the baseline diagnosis and follow-up of patients with NAFLD, such as liver aminotransferases and/or liver ultrasound [50–52].

Table 20.3 summarizes several studies that have used liver fat by MRS as the primary outcome of exercise-only interventions in patients with NAFLD. With some exceptions [53,54], all of them reported some reduction in hepatic steatosis after moderate exercise training [25–27,41,55]. Bacchi et al. [41] concluded that when aerobic and resistance exercise lead to a similar body weight reduction both are equally effective in reducing hepatic steatosis in patients with T2DM. In a recent study by Haus et al. [54] lack of weight reduction after 7 days of aerobic exercise resulted in no changes in total intrahepatic triglyceride content, emphasizing the importance of weight loss to achieve liver fat reduction. As can be appreciated in Table 20.3, most studies have been small and exercise alone (in the absence of weight reduction) was only moderately effective to reduce hepatic steatosis (∼10–20%) [25–27,54]. Patients who also lost weight had a greater reduction in liver fat content.

In a systematic review, Keating et al. [48] pooled data from 12 clinical trials involving 439 subjects. This work included an heterogeneous combination of studies that evaluated changes following physical activity on either liver aminotransferases, liver US, or hepatic fat content by MRS. Unfortunately, exercise intervention in most of the studies did not reach the minimal recommended exercise for the management of obesity and T2DM. While the effect on liver aminotransferases was inconsistent, the authors concluded that exercise alone had a small positive effect to decrease hepatic triglyceride accumulation in patients with NAFLD.

In summary, though the beneficial role of exercise per se has not been clearly demonstrated, there is no doubt that this intervention is beneficial in patients with NAFLD/NASH and/or T2DM, and that it should be recommended to patients in the management of NAFLD and NASH [13]. More work is clearly needed to establish the type, quality, and intensity of long-term exercise prescriptions in this population.

Combined dietary intervention and exercise

The available information on the role of combined lifestyle interventions (hypocaloric diets plus exercise) in patients with NAFLD is much more extensive, with several randomized, controlled trials showing significant benefit with this comprehensive approach [28,32,33,38,56–58]. Again, the overall reduction in liver fat reported in most of these trials has been

strongly correlated with the amount of weight loss. Table 20.4 summarizes the studies that have examined the effect of lifestyle intervention on liver fat by MRS. As expected, those studies that achieved a lesser degree of weight loss [28,31] had a smaller reduction in liver fat content. Of note, studies that have compared hypocaloric diet versus hypocaloric diet plus exercise have failed to report a significant difference in the improvement of liver fat content with the combined strategy, but in both studies weight loss was about the same with both interventions [28,56]. Keating et al. [48] reached a similar conclusion in a meta-analysis of all available studies, in which exercise plus diet had no significant pooled effect size (ES) when compared to diet alone (ES: −0.05; 95% CI −0.38–0.27, $p = 0.76$).

Table 20.4 Studies assessing the effect of dietary plus exercise intervention on liver fat content by MRS

An unresolved issue about many of these trials is whether small absolute changes in liver fat (even if of statistical significance) truly have clinical relevance. For instance, Lazo et al. [32] and Larson-Meyer et al. [57] reported apparently important reductions in liver fat content by MRS of 51% and ∼35%, respectively, but that reflected only a slight absolute change in hepatic steatosis (4.2% to 1.9% and 1.5% to 0.6%, respectively). It remains to be established if small absolute changes of intra-hepatic triglycerides within the normal range (note: NAFLD by MRS is defined as being >5.5%) translate into a true meaningful clinical benefit, or liver histologic improvement, in patients with NAFLD/NASH.

A few studies have performed liver biopsies before and after a weight loss intervention. As discussed earlier, histologic outcomes could be predicted by the magnitude of weight loss. In a 12-month uncontrolled study [59] using a standardized nutritional supplement combined with exercise counseling, failure to reduce weight was associated with no improvement in liver histology in the 15 (out of 23 enrolled) patients who completed the study. Consistent with the above, Eckard et al. [60] examined three different lifestyle interventions (low-fat diet or low-carbohydrate with moderate exercise or moderate exercise alone) compared to a standard care control group. Small study groups (11 to 12 per arm) and a high dropout rate (27%) limited the study conclusions. As in the previous study, failure to lose weight with diet and exercise (∼1% weight loss) translated into no major histologic improvement compared to the control group. In contrast, Promrat et al. [33] found that 48 weeks of lifestyle intervention (diet plus moderate exercise), that significantly reduced weight when compared to controls (9.3% vs. 0.2%, $p < 0.01$), markedly improved the NAFLD activity score (NAS) (-2.4 vs. -1.4, $p = 0.05$). Of note, this was mainly due to an improvement in steatosis (-1.1 vs. -0.3, $p = 0.02$), as lobular inflammation and ballooning were similarly improved in both groups, while fibrosis was unchanged. However, when the data was re-analyzed for subjects who had lost ≥7% of body weight, lobular inflammation and ballooning were significantly improved (as well as steatosis), underscoring the importance of the magnitude of weight loss to histologic benefit.

Although there are no large, long-term studies to assess the role of lifestyle intervention in patients with NAFLD/NASH, the importance of this strategy in the management of patients with NAFLD cannot be overemphasized. Weight loss achieved through different strategies appears to be the most important factor to improve plasma aminotransferases, liver fat content, and histology. The role of lifestyle changes in the absence of weight reduction is less clear and needs further assessment in well-designed studies.

Dietary intervention and weight-loss medications
Because long-term compliance with lifestyle interventions remains a major challenge, several investigators have examined the role of pharmacologic interventions to enhance weight loss in patients with NAFLD/NASH.

In a double-blind, randomized, controlled trial (RCT) by Zelber-Sagi et al. [61], 52 patients were randomized to lifestyle intervention ± orlistat for 6 months. After treatment there was no difference in weight loss between the two groups (-8% vs. -6%, $p = 0.26$). Histologic changes were similar in both groups. In another RCT in 50 obese patients with NASH, adding orlistat for 36 weeks to lifestyle intervention and vitamin E (800 UI daily) did not enhance weight loss (-8.3% vs. -6.0%, $p = \text{NS}$) or impact liver histology (primary endpoint) [62]. However, subjects who lost ≥5% of body weight markedly improved hepatic steatosis, while amelioration of liver necrosis and lobular inflammation required a body weight loss of at least 9%, suggesting that there is a lower threshold for steatosis resolution compared to other histologic parameters.

In summary, the role of the weight-loss medications tested to date in NAFLD is marginal. Large RCTs are much needed to assess the effectiveness of the recently FDA-approved weight management agents lorcaserin (Belviq®) and phentermine/topiramate extended-release (Qsymia®) in patients with NAFLD.

Surgically induced dietary intervention
The use of bariatric surgery as an alternative method to lose weight has become more popular in recent decades given the challenge of long-term weight loss. Different procedures are currently available and can be divided into three types: restrictive (reduction of gastric capacity), malabsortive (bypasses a segment of the small bowel), and hybrid procedures (combination of the above) [63]. Currently, the most popular procedures are *Roux-en-Y* gastric bypass (RYGB; hybrid) and laparoscopic adjustable gastric banding (LAGB; restrictive). There is large evidence on the effects of bariatric surgery on glucose control [64], insulin sensitivity [65], and overall improvement of related comorbidities (hypertension, dyslipidemia, and so on) [64] as well as positive effects on long-term survival [66]. However, the impact of these procedures on liver histology in patients with NAFLD has not been so extensively addressed. Moreover, most of the existing studies are retrospective, uncontrolled or have a small sample size [67–78].

Prospective studies [69–74,78] specifically assessing the role of RYGB have reported overall positive results with improvement in steatosis, inflammation, ballooning, and to a lesser extent fibrosis, after 12–24 months of follow-up. In some reports, histologic improvement led to complete NASH resolution [69,71,73]. Of note, in all of these studies there was a very significant body weight reduction after surgery. The main drawbacks of these studies, however, have been their sample size (7 to 19 patients, except for one study [78] that included 70 patients) and the lack of a control group. In addition, a few studies have reported that some patients develop new fibrosis after the surgical intervention [68,71,72]. As a consequence of these findings, there have been some concerns regarding the effect of bariatric surgery on hepatic fibrosis. Several hypotheses have been suggested to explain the potential mechanisms responsible

for worsening fibrosis in a subgroup of patients: rapid weight loss, lack of macro/micronutrients replacement or the direct effect of the procedure in a liver with pre-existing fibrosis. Of note, other series have not found any worsening of fibrosis in patients with NASH after bariatric surgery [69,73,74,78].

Regarding LAGB, although fewer studies have assessed its effect on histology in patients with NAFLD, studies are larger ($n = 36$ to 381) and many of longer duration (25–50 months) [75–77]. Similarly to RYGB, after major weight loss there is usually a significant improvement in steatosis, inflammation, and fibrosis. However, Mathurin et al. [77], in a large long-term follow-up study (381 patients followed for up to 5 years), found no change in hepatic inflammation and even a significant increase in fibrosis after one year, but without any further deterioration over time.

At present, there are no RCTs that have prospectively evaluated the best bariatric surgery approach for patients with NAFLD. It is also not well understood if the histologic changes after bariatric surgery in NASH are just the consequence of weight reduction or are secondary to other metabolic effects, such as changes in the gut microbiota or intestinal hormones. Further investigation is needed to determine the real long-term benefit of bariatric surgery in patients with NASH.

Pharmacologic agents

Statins

The role of statins in the primary and secondary prevention of CVD has been well established. Patients with NAFLD are believed to have increased cardiovascular risk [6] and are logical candidates for their long-term use. In accordance with their higher cardiovascular risk, the use of statins should be encouraged in patients with NAFLD but their use has remained controversial in such patients, particularly in the setting of elevated liver enzymes [5]. Recent practice guidelines on statin use in patients with NAFLD have clearly established that they are overall safe and that they do not carry a higher risk of liver toxicity [79,80].

In addition to their apparent safety in NAFLD, several small studies have suggested that statins may improve histology in NASH by means of their anti-inflammatory, antioxidant, or other pleiotropic properties [5]. Several studies reported that statins may decrease plasma aminotransferase concentration or hepatic steatosis by ultrasound [5,81,82]. However, it should be emphasized that these studies were overall of inadequate quality due to small sample size, uncontrolled design, short duration and/or lack of gold-standard endpoints, such as liver MRS or histology. In many of these trials effects were difficult to separate from weight loss, dietary changes or other lifestyle modifications during the study. In studies in which a liver biopsy was performed before and after statin treatment, Kimura et al. [83] ($n = 43$) and Rallidis et al. [84] ($n = 5$) found that liver inflammation improved, in contrast to reports from Georgescu

et al. [85] ($n = 10$) and Ekstedt et al. [86] ($n = 17$). Beyond these discrepancies, there is agreement that hepatocyte ballooning and fibrosis do not improve with statin therapy. In the only randomized controlled trial in patients with biopsy-proven NASH, Nelson et al. [87] reported a nonsignificant trend towards a reduction in plasma aminotransferase concentration but no changes in liver histology. However, the study was rather small ($n = 16$) and of relatively short duration (12 months).

Taken together, the evidence showing a beneficial effect of statins in NAFLD or NASH is weak and awaits well-designed long-term studies. Their use should be promoted to prevent cardiovascular disease, but not as a means for histologic improvement.

Fibrates

Recent large randomized controlled fibrate trials in patients with T2DM have failed to meet the primary outcome (reduction of a major cardiovascular or coronary event) when combined with statins [88,89]. However, post-hoc analyses have shown that patients with high plasma triglycerides (>200 mg dL^{-1}) and low HDL-C concentration may benefit from combined statin and fibrate therapy [90]. Patients with NAFLD are characterized by this type of dyslipidemia, and therefore, are good candidates for combination therapy.

As discussed earlier for statins, there has been substantial interest on the role of fibrates in NAFLD. Fibrates have many biologic effects on hepatic lipid metabolism (most mediated by PPAR-γ effects) that appear to support their potential role in NAFLD. Fibrates have been reported to improve plasma aminotransferase levels or decrease hepatic steatosis, but overall results have been inconsistent and histology unchanged [5]. In a study by Athyros et al. [91], atorvastatin plus fenofibrate in patients with NAFLD had no effect beyond that of ator-vastatin alone on plasma aminotransferase concentration or liver fat measured by ultrasound. In a well-designed RCT, two months of fenofibrate therapy had no effect on liver triglyceride accumulation when assessed by MRS [92].

In summary, fibrates are considered safe when needed for the prevention of cardiovascular disease in patients with NAFLD, but according to available evidence, they do not improve liver histology.

Ezetimibe

Ezetimibe has been evaluated in a few small studies in patients with NAFLD and atherogenic dyslipidemia. It has been reported to improve liver enzymes, inflammatory markers, and some histologic parameters [93,94]. In a randomized, single-blinded trial ezetimibe decreased liver fat by MRS but histologic outcomes were not examined [17]. However, these studies were small, open-label, or uncontrolled. Therefore, it is difficult to interpret whether these changes were the effect of ezetimibe therapy or just the consequence of weight reduction or lifestyle modification.

Pentoxifylline

Pentoxifylline is a nonselective phosphodiesterase inhibitor that reduces TNF-α and may affect other inflammatory pathways. Due to these anti-inflammatory effects, it has been considered as a potential treatment for NASH [95]. Although several studies have assessed the role of this drug in patients with NASH, just a couple of these were RCTs [95]. In one of such studies, Zein et al. [14] reported benefit on steatosis, inflammation, and fibrosis in 55 patients (46 with biopsy at the end of the study) randomized to pentoxifylline or placebo for one year. However, at baseline the two groups were not completely well matched, with patients in the pentoxifylline group having higher levels of AST/ALT and a trend towards worse histology. In another 12-month trial in 30 patients with NASH [15], pentoxifylline did not improve histology compared to placebo but decreased steatosis and ballooning against baseline. Once again, patients randomized to pentoxifylline had a worse baseline liver histology. Others studies assessing the role of this drug in NASH were either open-label, had a small sample size, or did not include histology or liver fat by MRS as endpoints [95]. Although the results with pentoxifylline are encouraging (especially the results of Zein et al. showing an improvement in fibrosis), much more work remains to be done to clearly understand the true role of this drug in NAFLD.

Omega-3 polyunsaturated fatty acids

Omega-3 polyunsaturated fatty acids (PUFAs) have been proposed as a potential therapy for liver steatosis [96]. They have been shown to activate PPARα receptors, which upregulate several genes involved in fatty acid oxidation and at the same time downregulate pro-inflammatory genes [97]. Moreover, PUFAs activate PPARγ, which also increases fat oxidation. Other important effects of PUFAs include reduction of endogenous lipid production and inhibition of hepatic glycolysis. Animal models have shown not only that low-PUFA diets promote steatosis and insulin resistance, but also that supplementing diet with PUFAs can prevent and even reverse hepatic steatosis [97]. Although several studies have examined the role of these compounds in humans, most of these studies have significant study design limitations [98,99], such as being open-label and lack of proper controls, or use as the primary outcome improvement of liver enzymes or liver fat by ultrasound. In the only RCT with PUFAs, Cussons et al. [100] reported a small, but statistically significant, reduction in hepatic steatosis by MRS. However, as discussed earlier, the meaning from a clinical standpoint of a small reduction in liver triglyceride content (from 10.2% to 8.4%) remains uncertain. Also, just one study assessed the effect of PUFAs on liver histology, but was small ($n = 23$) and uncontrolled [101]. Therefore, based on the available evidence it is difficult to make a final conclusion in regard to the role of PUFAs in NAFLD. Larger, well-designed RCTs are needed to understand their true effects in this disease.

Vitamin E

Vitamin E is an antioxidant believed to reduce hepatocyte oxidative stress in patients with NASH [102–105]. Several small studies of short duration in patients with NASH have reported inconsistent results [102–104,106–108]. In nondiabetic patients with biopsy-proven NASH [11] vitamin E led to a 43% response in the primary histologic endpoint compared to 19% in the placebo group ($p = 0.001$). The primary histologic endpoint was an improvement in ≥2 grades in the NAS with at least one point improvement in hepatocellular ballooning and one point in either the steatosis or lobular inflammation score, with no worsening of fibrosis.

In summary, vitamin E may be beneficial in patients with NASH without T2DM because it appears safe and is relatively inexpensive, but its long-term efficacy (beyond 2 years) has not been established. Moreover, its use in patients with diabetes and NASH has never been studied and remains to be established.

Glucose-lowering agents

Metformin

Metformin is a biguanide that has been used worldwide for more than 50 years for the treatment of T2DM although its exact mechanism of action remains incompletely understood. It decreases hepatic glucose production and improves insulin sensitivity at the level of the liver, and to a lesser extent, muscle [109]. Metformin has been reported to reduce plasma aminotransferase levels in patients with NAFLD [104,110–112]. Early small studies suggested that metformin improved hepatic steatosis, necro-inflammation and/or fibrosis in patients with NASH [104,113,114], but not in more recent and better controlled clinical trials [115].

Taken together, although metformin is not recommended as a specific treatment for patients with NASH [13], it still has significant clinical value to control hyperglycemia and reduce cardiovascular risk in patients with prediabetes or T2DM and NASH [116].

Glucagon-like peptide 1 agonists

Glucagon-like peptide 1 (GLP-1) analogues have become widely used in patients with T2DM and their beneficial effects have been quite consistent across studies in this population [117,118]. Although their role in NAFLD is more uncertain, recent studies have suggested a therapeutic potential for these pharmacologic agents in NAFLD. In animal models, exendin-4 has been reported to improve both liver function tests and histology [119,120]. Moreover, *in vitro* studies have shown that human hepatocytes express the GLP-1 receptor and that GLP-1 analogues suppress hepatic lipogenesis and pro-inflammatory mediators [121]. In humans with hepatic steatosis, open-label studies have shown that exenatide may improve liver enzymes and decrease steatosis when assessed by MRS [122,123], and even improve histology [124]. In a randomized, open-label trial by Sathyanarayana et al. [125], the combination of pioglitazone

and exenatide improved transaminases and liver triglyceride accumulation by MRS beyond that of pioglitazone alone. In patients with T2DM treated with metformin, Jendle et al. [126] found that the GLP-1 analogue liraglutide added to metformin improved liver aminotransferase concentration and liver fat by computed tomography (CT) significantly more than the addition of glimepiride to the biguanide. Despite these promising results, the underlying mechanisms remain unclear and the relative contribution of direct GLP-1 agonism on the liver, versus weight loss or better glycemic control per se, demand further investigation in well-designed studies.

Thiazolidinediones (TZDs)

Thiazolidinediones (TZDs) are glucose-lowering agents that act as insulin sensitizers in humans. They are ligands for the transcription factor peroxisomal proliferator activated receptor-γ (PPAR-γ) that plays key roles in the regulation of metabolic homeostasis and inflammation. PPAR-γ is predominately expressed in adipose tissue, but is also present in the pancreas, liver, spleen, heart, and muscle [127]. In NASH, TZDs improve adipose tissue and hepatic insulin sensitivity, reduce subclinical inflammation, and restore liver histology [115,128].

Both pioglitazone and rosiglitazone have been studied in NAFLD/NASH [129]. Most of the early studies were heterogeneous in terms of baseline patient characteristics and showed inconsistent clinical efficacy [103,112,130–132]. However, across these studies TZDs usually led to improved insulin sensitivity, reduced liver fat content, and normalization of plasma aminotransferase levels [103,130,133].

In patients with biopsy-proven NASH, the efficacy of TZDs, and especially of pioglitazone, has been examined in several studies (Table 20.5). The first RCT was reported in patients with prediabetes or T2DM and NASH [10]. In this population, pioglitazone (45 mg day^{-1}) significantly reduced insulin resistance at the level of the liver, adipose tissue and skeletal muscle, and improved hepatic steatosis, inflammation and hepatocellular ballooning when compared to placebo. In 73% of patients treated with pioglitazone, the NAFLD activity score improved compared to 24% in the placebo group ($p < 0.001$).

A larger study later extended these findings to patients with NASH but without diabetes [11]. They randomized 247 subjects to vitamin E, pioglitazone, or placebo and found histologic improvement in liver steatosis and inflammation but not fibrosis after pioglitazone treatment. On the other hand, Ratziu et al. [132] evaluated the use of rosiglitazone in patients with NASH and reported more modest results, with only a ∼20% reduction in hepatic steatosis on histology but no improvement in lobular inflammation, ballooning, or fibrosis.

Confirmation about TZDs' long-term benefit is needed because the studies have been of relative short duration (6 to 24 months). In a preliminary report in patients with T2DM and prediabetes, Cusi et al. [134] have reported that after 18 months of treatment more subjects had improvement with pioglitazone compared to placebo for liver steatosis (75% vs. 29%, $p < 0.001$), ballooning (55% vs. 26%, $p < 0.01$), and inflammation (53% vs. 26%, $p = 0.01$), as well as in the NAFLD activity score (NAS) (83% vs. 38%, $p < 0.001$). Moreover, pioglitazone had a modest but significant effect on fibrosis compared to placebo ($p = 0.03$) and baseline fibrosis stage ($p < 0.01$).

With pioglitazone being the only TZD available in the United States and most countries, it must be kept in mind that while an effective drug for T2DM and NASH, caution must be exerted about its off-target effects (Figure 20.1) [135]. Thiazolidinediones have the potential to exacerbate congestive heart failure and promote water retention. Moreover, its use has been associated with a greater risk of osteoporosis and bladder cancer. In a meta-analysis of 19 trials in 16,390 patients with T2DM [136], the rate of congestive heart failure was noted to be slightly higher in pioglitazone users versus control patients using other oral agents for diabetes (2.3% vs. 1.8%, HR 1.41; 95% CI 1.14–1.76; $p = 0.002$). However, there was also a significant reduction in the combined outcome of death, myocardial infarction, or stroke ($p = 0.005$). Pioglitazone has been associated with bladder cancer, and currently the FDA recommends avoiding it if active bladder cancer is present, and use with caution if there is a prior history of the disease. However, a recent 8-year interim analysis (from January 1, 1997 to December 31, 2010) reported a trend for

Table 20.5 Histologic outcomes in randomized, placebo-controlled trials assessing the efficacy of pioglitazone in patients with NASH

Author (year)	n	Duration (months)	Dose (mg)	Patients with diabetes	Patients with histologic improvement			
					Steatosis	Inflammation	Ballooning	Fibrosis
Belfort [10] (2006)	55	6	45	Yes	65%**	65%**	54%*	NS
Aithal [131] (2008)	74	12	30	No	NS	NS	32%**	29%*
Sanyal[a] [11] (2010)	247	24	30	No	69%**	60%**	44%#	NS
Cusi [134] (2013)	101	18	45	Yes	75%**	52%*	55%**	40%#

Diabetes, type 2 diabetes mellitus; NS, not significant.

[a]Study had a third arm with vitamin E 800 UI (see section on vitamin E).

*$p \leq 0.05$ and

**$p < 0.01$ when compared against the control group.

#Change not statistically significant compared to control group, but there was a statistically significant difference when change in mean scores was compared.
Figure 20.1 Metabolic and cardiovascular effects of thiazolidinediones in humans. Source: Yau 2013 [135]. Reproduced with permission of Springer.

the risk of bladder cancer to be less over time, with hazard ratios (HR) that were nonsignificant in fully adjusted models that included key variables such as tobacco use, duration of pioglitazone therapy, or cumulative pioglitazone dose (Clinical Trial NCT01637935). For example, duration of therapy with pioglitazone for more than 2 years (HR = 1.4; 95% CI 1.03–2.0) or 4 years (HR = 1.62; 95% CI 0.96–2.74) in the 5-year analysis was higher than the 8-year analysis (HR = 1.30; CI 0.91–1.86, NS). Similarly, cumulative doses of pioglitazone >28,000 mg in the 5-year analysis (HR = 1.43; CI 0.96–2.12) did not continue to increase the risk of bladder cancer in the 8-year analysis (HR = 1.25; CI 0.91–1.74, NS). Recent guidelines from the American Association for the Study of Liver Diseases, American College of Gastroenterology, and the American Gastroenterological Association [13] recommend the use of pioglitazone as a valid alternative for the management of patients with biopsy-proven NASH in patients with diabetes. However, there is clearly a need for more studies to evaluate

its long-term efficacy and safety. Careful patient selection is crucial in order to maximize benefits while reducing the risks associated with pioglitazone use, as recently reviewed elsewhere [135].

Obeticholic acid (OCA)

Obeticholic acid, a derivative of the primary human bile acid chenodeoxycholic acid, is an agonist of the farnesoid X receptor (FXR: a key nuclear receptor that regulates hepatic glucose and lipid metabolism). In a small study [137], OCA was found to only marginally ameliorate insulin resistance. Improvements in insulin sensitivity and liver aminotransferases only occurred at doses of 25 mg, but not at higher doses (50 mg). The same was true for plasma markers of inflammation and fibrosis. However, in early 2014, a RCT of OCA (25 mg day^{-1}) versus placebo in patients with biopsy-proven NASH was stopped early during an interim analysis because of significant positive results on liver histology. In data from about half of the 283 randomized

patients, it was concluded that OCA led to a highly significant improvement in histology according to an intention-to-treat analysis. However, long-term data is still needed to fully assess its safety and efficacy.

Future directions

Increased awareness among healthcare providers will be needed for the early diagnosis and optimal management of the patient with NAFLD/NASH. Patient care will entail going beyond liver-specific complications to embrace a comprehensive strategy that ameliorates obesity-induced lipotoxicity while addressing associated comorbidities, such as T2DM or CVD. Reminding ourselves that the condition is really that of a chronic "lipotoxic liver disease" helps highlight the crosstalk between dysregulated adipose tissue and the liver, be more aware of its chronic nature and the need for a long-term management plan. It is likely that diagnosis accuracy will improve in the near future with a combination of more specific plasma biomarkers, advances in genetic testing and better metabolic profiling (i.e., metabolomics approaches).

Earlier and more accurate disease staging will allow targeting therapy earlier and direct it only at patients with a greater risk of disease progression. Therapies that relieve the liver from systemic lipotoxicity by targeting adipose tissue insulin resistance and inflammation (e.g. significant weight loss, exercise, and/or pioglitazone) hold reasonable chances of long-term success. However, new and more effective approaches will be needed. One can envision the need for combining agents that target different defects, much like what we do today for T2DM or hypertension. Multiple agents are undergoing testing in RCTs for the treatment of NASH (see https://clinicaltrials.gov/). The different approaches proposed include "hepatoprotective" agents such as silymarin (milk thistle) or the antibiotic rifaximin. They are believed to improve the deleterious gut flora present in obesity and NAFLD and mediate positive changes in insulin sensitivity. Novel insulin-sensitizers such as resveratrol (an antioxidant), fenretinide (antagonize insulin action), or the new adenosine monophosphate-activated protein kinase (AMPK) activators (oltipraz) that improve insulin sensitivity and fatty acid synthesis, are undergoing investigation. Other approaches include the antioxidant S-adenosyl-L-methionine (SAMe), aimed at reducing lipid peroxidation and secondary cellular injury.

Until we find the optimal long-term lifestyle and pharmacologic approach for NAFLD in T2DM, based on the evidence reviewed, the clinician must remain alert and offer an integrated management plan to the increasing number of patients with this chronic and relentless liver condition.

Key points

- Epidemiology demonstrates an association between obesity, type 2 diabetes and increased cancer risk and cancer-related mortality.
- Numerous potential factors may be causal such as insulin, IGFs, glucose, lipids, adipokines, and inflammatory cytokines.
- Mouse models are a valuable to tool to study potential causal factors.

Introduction

An association between hyperglycemia, diabetes, and cancer has been recognized for many years. Epidemiologists first noted the association between diabetes and cancer in the early part of the twentieth century, while the association between hyperglycemia and cancer was reported in 1885. At that time, in Europe and North America life expectancy was improving, rates of over-nutrition and under-exercise were increasing, there was a rise in the percentage of people that were overweight, and the incidence of diabetes began to climb [1]. The epidemiologists and statisticians of the time examined the association between diabetes and cancer in different populations to determine if there was truly a relationship between these conditions, or if the association was purely related to increased longevity. Their studies found that although both conditions increased with age, diabetes appeared to increase the risk of cancer, independent of age. Meanwhile, physicians had observed differences in glucose homeostasis in individuals with cancer, and researchers such as Otto Warburg were studying the distinct metabolic properties of cancer cells, namely the generation of energy by the fermentation of glucose [2]. Since these early discoveries, a wealth of research has been conducted in the field of diabetes and cancer. Today, in the setting of the global diabetes and obesity epidemics, understanding the epidemiologic links between diabetes and cancer and determining the mechanisms through which these conditions are linked has become a priority for research, in order to prevent and treat cancers that are more likely to occur in those with diabetes.

Epidemiology

Epidemiologic studies continued through the twentieth century, with reports of a link between diabetes and the development of pancreatic, endometrial, breast cancer, and hematologic malignancies. However, until the 1990s much of the epidemiologic findings were inconsistent due to many confounding risk factors that were not accounted for in studies, such as obesity, smoking, and hormonal therapy as well as differences in study design. From the 1990s to present, large prospective cohort studies have been conducted, such as the Cancer Prevention Study II (CPS II), the Physicians' Health Study and the Women's Health Initiative (WHI) in the USA, and the European Prospective Study into Cancer. In these studies individuals were recruited, data including the presence or absence of diabetes, body mass index (BMI), smoking status, were collected along with serum samples. Participants were then followed for a number of years to determine whether they developed cancer or died from cancer. These studies reported an increased incidence of cancer in individuals with diabetes, and an increased mortality in those with diabetes who develop cancer.

Although many of these studies did not specifically record diabetes type, in the US of adults with diabetes, 90–95% have type 2 diabetes (T2DM). Therefore, at least 90% of the populations in these studies would have T2DM. In contrast to T2DM, the studies into the risk associated with type 1 diabetes (T1DM) and cancer have been largely inconsistent. One major potential reason for variable results is that the majority of studies use either insulin therapy or age cut-offs to define T1DM. These age cut-offs vary widely from under 18 years of age to under 40

---

years of age; therefore, individuals with type 2 diabetes are very likely to be included in some of these studies. In addition, these studies are a mixture of cohort and case-control studies, which may also contribute to the variable results. With these limitations in mind, individual studies have reported an increased risk of pancreatic, liver, mouth and pharyngeal, stomach, skin and ovarian cancer, as well as leukemia in those with T1DM. The types of cancers that are associated with T1DM are not consistently reported between the studies, and some studies report no association between diabetes and cancer [3].

While the overall risk of cancer is greater in those with T2DM, several studies and meta-analyses have examined which cancers are specifically affected by diabetes. While the earliest epidemiologic studies demonstrated a significantly increased risk of pancreatic cancer in those with diabetes, it was later noted that there was a close temporal relationship between the onset of diabetes and the diagnosis of pancreatic cancer; in fact the development of hyperglycemia and diabetes may be a manifestation of undiagnosed pancreatic cancer, this effect is known as "reverse-causation." More recent studies have excluded individuals who develop cancers within 5 years of the start of the study in an attempt to avoid this effect and these studies have demonstrated an increase in the risk of pancreatic among other cancers in those with T2DM [4]. The results of the meta-analyses examining specific cancer sites and T2DM are summarized in Table 21.1. Individuals with diabetes have approximately twice the risk of hepatocellular, endometrial, and pancreatic cancer than those without diabetes [5–7]. The risk of biliary tract and renal cancer appear to be increased by 40% and bladder cancer by approximately 20% in those with diabetes [8–10], while the risk of breast cancer is increased by 20% in women and colorectal cancer is increased by 30% in both sexes [11,12]. The

risk of esophageal cancer may be increased in men with diabetes, while the risk of certain brain cancers and gastric cancer may be increased in women with diabetes [13–15]. The most notable exception to the general increased risk of cancer is with prostate cancer; epidemiologic studies and meta-analyses have reported a decreased risk of developing prostate cancer in men with diabetes [16,17]. However, in some studies for prostate cancer, similar to those in breast and colorectal cancer, diabetes has been associated with a greater mortality risk, a greater risk of treatment failure, and higher recurrence rate. The majority of studies have been conducted in the US and Europe; however, the results are not necessarily applicable to other populations (Asian, African, and Hispanic) where the prevalence of diabetes, obesity, and different types of cancer varies (e.g. hepatocellular and esophageal cancer is more common in Asia, and other factors may outweigh any increased risk from diabetes). Studies are now being conducted in different racial and ethnic groups in different countries to determine whether the risk associated with diabetes is applicable worldwide. As set out in Table 21.1, meta-analyses have shown that individuals from Asia with a history of diabetes have no increased risk of esophageal cancer (in contrast to the European population), while similar to other groups they do have an increased risk of hepatocellular cancer, and in contrast to other ethnic groups may have an increased risk of prostate cancer [7,14,17]. Although there is substantial evidence supporting the link between diabetes and the more common epithelial cancers, there is less information available on the less common cancers [4]. These cancers are more difficult to study in large epidemiologic studies, due to their lower incidence in the general population and therefore longer follow-up and larger studies are needed to determine whether diabetes increases the risk of some of the less common cancers.

Table 21.1 Meta-analyses examining specific cancer sites and T2DM

Cancer site	Overall relative risk (95% CI)	Male relative risk (95% CI)	Female relative risk (95% CI)	Reference
Liver	2.31(1.87–2.84) 2.00(1.46–2.75)[a]	2.03(1.58–2.62)	1.91(1.22–2.99)	[7]
Endometrium		N/A	2.10 (1.75–2.53)	[6]
Pancreas	1.83 (1.38–2.43)[b]	1.70 (1.55–1.87)	1.60 (1.43–1.77)	[5]
Biliary tract	1.43 (1.18–1.72)	1.31 (1.17–1.47)	1.29(1.13–1.46)	[10]
Kidney	1.42(1.06–1.91)	1.26 (1.06–1.49)	1.70 (1.49–1.97)	[8]
Colorectal	1.30 (1.20–1.40)	1.29 (1.15–1.44)	1.33(1.23–1.44)	[11]
Esophagus	1.30(1.12–1.50) 1.26 (0.91–1.75)[a]	1.28(1.10–1.49)	1.07(0.71–1.62)	[14]
Bladder	1.24 (1.08–1.42)	Not reported	Not reported	[9]
Breast	Not reported	1.29 (0.99–1.67)	1.20 (1.13–1.29)	[12]
Brain	1.12 (0.89–1.42)	1.02 (0.94–1.12)	1.24 (1.03–1.50)	[13]
Stomach	1.09(0.98–1.22)	1.04(0.94–1.15)	1.18(1.01–1.39)	[15]
Prostate		0.86 (0.80–0.92) 1.31 (1.12–1.54)[a]	N/A	[17]

[a] Asian population.
[b] Diabetes duration of at least 5 years before the diagnosis of pancreatic cancer.

In the CPS II study of 1,053,831 individuals after 26 years of follow-up, increases in mortality from less common cancers such as male breast cancer (fourfold increased risk) and oral and pharyngeal cancers (40% increased risk) were observed in those with diabetes. It should be noted that many studies report an increased risk of mortality in patients with cancer who have diabetes, but any individual with diabetes has almost doubled the age-adjusted mortality of someone without diabetes. Therefore, whether diabetes increases cancer-specific mortality because of more aggressive cancer growth and spread, or whether the increased mortality is merely a reflection of the overall increased mortality seen with diabetes remains unclear [4].

Links between diabetes and cancer

Common risk factors

Epidemiologic studies demonstrate that those with diabetes are more likely to develop cancer, but the mechanisms through which this may occur are incompletely understood. The American Diabetes Association and the American Cancer Society published a consensus report in 2010, with the aim of examining the knowledge regarding the association between diabetes and cancer, exploring the risk factors for both conditions, to examine their possible biologic links and to determine whether certain treatments for diabetes modify cancer risk [4]. In the report they identified certain risk factors that increase the chance of developing both conditions. These were listed as "non-modifiable" and "modifiable" risk factors that are common to diabetes and cancer and may explain in part the increased risk of cancer. Non-modifiable risk factors include age, sex, and race/ethnicity. While modifiable risk factors include overweight/obesity, smoking, alcohol intake, and physical activity and diet (Table 21.2). In addition there are biologic factors that may be common to the two conditions. With advancing age the risk of both T2DM and cancer increase: 78% of newly diagnosed cancers occur in those over 55 years of age, the prevalence of diabetes also increases with age, from 10.8% in those aged 40–59 years, but increases to 23.8% in those aged 60 years or more. Men have a slightly higher risk of developing diabetes than women, additionally, with the exception of certain sex-specific or almost sex-specific cancers (e.g. prostate, testicular, cervical, endometrial, and breast cancer), men are also more likely than women to develop cancer. Certain racial groups (e.g. African Americans) are more likely to develop cancer and diabetes than other racial groups. Overweight and obesity have been associated with cancers for many years. Large epidemiologic studies, including the Cancer Prevention Study II in the USA and the Million Women's Study in the UK reported that for both men and women an increased body mass index (BMI) was associated with a greater risk of developing colorectal, esophageal, pancreatic, and kidney cancer, non-Hodgkin's lymphoma and multiple myeloma; additionally they reported an increased risk of endometrial cancer, ovarian cancer, and postmenopausal breast cancer in women. In fact the results of the CPS II study suggest that 14% of cancer deaths in men and 20% in women could be attributed to obesity. Currently over a third of Americans are obese. Overweight and obesity also increase the risk of developing T2DM. A number of studies have now shown that smoking is an independent risk factor for developing T2DM and is also a risk factor for multiple cancers. Moderate to high alcohol consumption is known to increase the risk of certain cancers and in certain populations, such as in lean Japanese individuals moderate to high alcohol intake is also a risk factor for the development of diabetes [18]. A sedentary lifestyle is associated with an increase in many chronic diseases, amongst them are diabetes and cancer. Finally, consuming a diet rich in fruits and vegetables has been shown in studies to be protective against the development of T2DM and cancer.

Biologic links

Identifying the increased risk of cancer in those with T2DM or obesity let to the hypothesis that there must be common biologic links between these conditions that increase the risk of cancer. Additionally, recent studies have shown that those with the metabolic syndrome, a syndrome on the continuum between obesity and T2DM also have an increased risk of cancer. Physiologic changes that may occur in individuals with obesity, the metabolic syndrome and T2DM and may contribute to cancer development include hyperglycemia, insulin resistance and hyperinsulinemia, increased insulin-like growth factor-I (IGF-I) levels, dyslipidemia, visceral adiposity and increased inflammatory cytokines, altered levels of circulating adipokines, and altered circulating and tissue levels of estrogens (Table 21.3). Epidemiologic and animal studies have been conducted to examine these individual biologic factors on cancer development.

Table 21.2 Risk factors that increase the chance of developing type 2 diabetes or cancer

Non-modifiable	Modifiable
Age	Overweight/Obesity
Sex	Smoking
Race	Alcohol
	Physical activity
	Diet

Table 21.3 Potential biologic links between type 2 diabetes and cancer

- Hyperglycemia
- Hyperinsulinemia
- IGF-I
- Dyslipidemia
- Inflammatory cytokines
- Adipokines
- Circulating and tissue estrogen levels

Hyperglycemia

It is well known that cancers take up glucose, a phenomenon that is exploited in the visualization of fluorodeoxyglucose (FDG) uptake by positron emission tomography (PET) for the detection of tumors and metastases. Some epidemiologic studies have examined how glucose levels alter cancer risk. A European study of individuals with the metabolic syndrome (The Me-Can study) found that higher glucose levels were associated with an increased risk of liver, gallbladder, respiratory, thyroid cancer, and multiple myeloma in men, as well as pancreatic, bladder, endometrial, cervical, and stomach cancer in women. However, in a meta-analysis of prospective diabetes studies (VADT, ACCORD, UKPDS33, UKPDS34), complications were compared in patients receiving intensive glucose control and A1c values of 6.9%, 6.4%, 7%, and 7.9% with those receiving standard diabetes control and A1c values of 8.4%, 7.5%, 7.9%, and 8.5%, respectively. They determined that there was no difference in cancer outcome between the standard and intensively controlled groups. These studies were not designed to examine cancer incidence as a primary outcome; some of the treatments for diabetes may potentially have increased the risk. Additionally, all of the patients in these studies had a diagnosis of diabetes, and therefore were all at potentially increased risk of cancer as well as having abnormal glucose levels, compared to the normal nondiabetic population. Other prospective studies on over 60,000 individuals in the Vasterbotten Intervention Project in Sweden and the Hong Kong diabetes registry did report an increased risk of cancer in those with hyperglycemia. Thus, human studies assessing the effect of hyperglycemia on tumor growth are inconclusive due to confounding biologic and diabetes treatment effects.

Insulin and IGF-I

In many of the previously mentioned prospective epidemiologic studies, such as the WHI, the Physicians' Health Study and the EPIC studies, serum samples were stored at the time of recruitment and these samples were subsequently analyzed to determine whether there was an association between a specific biomarker (e.g. endogenous insulin levels) and the risk of certain cancers. In the WHI study insulin levels were measured in the study population and then the population was divided into quartiles based on their endogenous insulin levels. Comparing those with insulin levels in the highest quartile with the lowest quartile, they found that women with higher insulin levels who did not take hormone replacement had a greater risk of breast cancer. The Nurses' Health Study II, which consisted mostly of premenopausal women, did not find an association between insulin and premenopausal breast cancer. C-peptide is used in some studies as a marker of endogenous insulin secretion. Higher C-peptide levels have also been associated with postmenopausal breast cancer. In the Physicians' Health Study and the Nurses' Health Study higher levels of C-peptide were associated with an increased risk of colorectal cancer. Subsequent studies have also reported that high plasma C-peptide levels are associated with colonic adenomas, suggesting that hyperinsulinemia may act as an early etiological factor in the development of colon cancer. A meta-analysis of studies reported that individuals who develop colorectal and pancreatic cancer have increased prediagnostic insulin/C-peptide levels. Interestingly, the Physicians' Health Study also found that high C-peptide levels were associated with an increased risk of prostate cancer and prostate cancer mortality. In a study from Finland, fasting insulin concentrations were higher in men who subsequently developed prostate cancer, an association that was independent of glucose levels. Some variability in results has been observed in studies on insulin/C-peptide and cancer risk and data are only available on a few cancer types. Many of these studies did not collect serum for insulin and C-peptide in fasting conditions, and these samples were collected and stored for many years long before analysis and before the development of cancer, therefore these may contribute to some variability between the epidemiologic studies.

Hyperinsulinemia directly increases hepatic IGF-I expression via the IR and leads indirectly to increased hepatic IGF-I production, by increasing hepatic growth hormone receptor levels. Growth hormone then acting through the growth hormone receptors stimulates IGF-I expression. High normal levels of circulating IGF-I are associated with increased risk of certain cancers including colorectal, breast, and prostate cancer in prospective epidemiologic studies and meta-analyses [19–21]. No association has been found between circulating IGF-I and lung cancer.

Dyslipidemia

The relationship between cholesterol and cancer risk has been difficult to discern from epidemiologic studies. Individuals with the metabolic syndrome and T2DM frequently have a dyslipidemic profile with elevated triglycerides and decreased high-density lipoprotein cholesterol (HDL-C). In the Metabolic Syndrome Cancer (Me-Can) European cohort elevated triglyceride levels were associated with colon, respiratory, kidney, thyroid cancers, and melanoma in men and respiratory, cervical, and nonmelanoma skin cancers in women [22]. An inverse relationship was found between elevated HDL-C and incident cancer risk in a meta-analysis of 24 randomized control trials, with inverse relationships also being found for both prostate and breast cancer risk. A recent Danish population study reported that the use of statins before the diagnosis of cancer was associated with reduced cancer-related mortality compared to nonusers of statins [23]. There is a relative dearth of studies examining the association between cholesterol and cancer, as elevated cholesterol is associated with such significant increases in cardiovascular mortality that many individuals died of cardiovascular disease before developing cancer. Additionally, caution should be applied when interpreting studies on cholesterol and cancer as low cholesterol levels are associated with chronic diseases, thus individuals with metastatic lung cancer may have low cholesterol levels, which

may be a cause of the chronic illness rather than low cholesterol levels being associated with metastatic lung cancer. Further epidemiologic studies in the area of cholesterol and cancer are necessary to determine whether a true association between these conditions exists.

Inflammatory cytokines and adipokines

Abdominal obesity is considered a state of chronic inflammation and this inflammation is often thought to contribute to the insulin resistance that leads to the development of the metabolic syndrome and T2DM. Macrophages found in adipose tissue secrete inflammatory cytokines including interleukin-6 (IL-6) and tumor necrosis factor alpha (TNF-α) and these cytokines have also been implicated in the development of numerous cancers. Examination of serum TNF-α and IL-6 levels in the EPIC cohort have found that higher circulating levels of these cytokines were associated with a significantly increased risk of endometrial cancer; however, adjusting for body mass index resulted in a loss of a significant association between IL-6 and endometrial cancer. This should not be considered surprising as the increase in inflammatory cytokines is thought to be associated with increased adiposity.

The circulating levels of the adipokine leptin increase in the setting of obesity, the metabolic syndrome, and T2DM, while circulating levels of adiponectin decrease. High leptin levels and low adiponectin levels have been associated with certain cancers, although epidemiologic studies have shown inconsistent results. In a cohort from the WHI, low adiponectin and high leptin levels were associated with an increased risk of colorectal cancers; however, the effect of low adiponectin was not independent of insulin. Low adiponectin has also been associated with an increased risk of breast, renal, and prostate cancer as well as multiple myeloma in some studies. Although leptin is hypothesized to increase tumor growth, the Physicians' Health Study found no association between leptin and prostate cancer; no association has been found between leptin and renal cancer or multiple myeloma in the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial, and the Nurses' Health Study found that leptin levels were inversely associated with premenopausal breast cancer risk. Overall, these epidemiologic studies suggest that both inflammatory cytokines and adipokines may be playing a role in the development of cancers in individuals with obesity, the metabolic syndrome, and T2DM. Whether these effects are independent of insulin remains to be determined.

Altered estrogen levels in T2DM and cancer

Obese postmenopausal women are known to have higher circulating levels of estrogen than their lean counterparts due to increased aromatase activity in adipose tissue. Additionally, obese insulin-resistant women have decreased hepatic production of sex hormone-binding globulin (SHBG) leading to more bioavailable estrogens in the circulation. Recent studies have shown that in the breast tissue from obese individuals, aromatase expression is increased approximately twofold, compared to the expression level in the breast tissue of normal weight women [24,25]. This increased expression may lead to higher estrogen concentrations in the breasts of obese women and may drive the growth of tumors that are hormone responsive, such as common postmenopausal breast cancers.

Overall, epidemiologic studies have demonstrated a consistent increase in the risk of many epithelial cancers in those with T2DM. Many risk factors have been identified that are associated with an increased risk of both T2DM and cancer development. Biologic links that are known to be associated with obesity, the metabolic syndrome, and T2DM have been identified, including hyperinsulinemia, increased IGF-I, dyslipidemia, inflammatory cytokines, adipokines and estrogens, and the association between these factors and cancer have been explored in epidemiologic studies. However, the current epidemiologic studies cannot directly determine whether these factors can actually cause cancer or increase tumor growth, or the mechanisms through which they may exert these effects. Therefore, animal models have been created in order to understand the links between diabetes and cancer.

Animal studies

In experimental studies, type 1 and type 2 diabetes have a different impact on tumor growth

A few decades ago it was shown that chemical destruction of pancreatic β cells with the subsequent development of T1DM suppresses tumor growth, whereas administration of exogenous insulin stimulates malignant growth in tumor-bearing animals with T1DM [26]. In addition, intraportal transplantation of pancreatic islets into rats with T1DM results in the development of an insulin-enriched microenvironment promoting hepatocellular tumor growth. Furthermore, in a model of pancreatic islet transplantation it has been shown that insulin-driven hepatocarcinogenesis is mediated by the PI3K/Akt/mTOR pathway and can be effectively inhibited by NVP-BEZ235, a dual PI3K/mTOR inhibitor. Taken together, the results of these studies indicate that (i) insulin is capable of stimulating tumor growth, (ii) T1DM is associated with a suppressed tumor growth, and (iii) hyperglycemia per se does not promote tumor growth, at least in the setting of insulinopenia.

The relationship between T2DM and cancer is much more complex. Most individuals with T2DM are overweight and/or obese, and each of the individual diabetes- and adipose tissue-related factors (hyperinsulinemia, hyperglycemia, hyperlipidemia, adipokines, cytokines, chemokines, and growth factors) is capable of stimulating tumor growth.

Most experimental studies investigating the link between T2DM and cancer were performed in rodent (primarily mouse) models of genetically induced and diet-induced obesity and T2DM. However, a lot of insight into the mechanisms that link T2DM and cancer was obtained from cancer studies conducted in models of obesity-independent T2DM.

Genetically induced obesity and cancer

Under experimental conditions, obesity in rodents is frequently induced by a genetic disruption of leptin signaling. Leptin interacts with a cognate receptor in hypothalamic neurons to decrease appetite and regulate energy homeostasis and thermogenesis. Rodent models of genetically induced obesity have been extensively used to study the relationship between obesity and/or insulin resistance and cancer.

The spontaneously occurring lethal yellow, or yellow agouti (A^Y), mouse strain is one of the first rodent models in which an association between increased body weight and a higher susceptibility to tumor development has been noted [27]. Later, a few new yellow mutations have been identified, including the viable yellow (A^{vy}) mutation, which in contrast to the A^y mutation, is not lethal when inherited homozygously. The yellow mice (A^y, A^{vy}) have a multifaceted phenotype which includes obesity, insulin resistance, enhanced linear growth, and susceptibility to tumor formation. The obese phenotype in the yellow mouse is caused by expression of abnormal agouti protein resulting in blockade of hypothalamic melanocortin-4 receptors, which are involved in the regulation of feeding behavior and energy homeostasis. However, the increased tumor growth in these mice should be interpreted with caution as several lines of evidence indicate that ectopic expression of agouti is capable of promoting chemically induced carcinogenesis independent of obesity and hyperinsulinemia [28].

The Lep^{ob}/Lep^{ob} (ob/ob) mice bear a naturally occurring autosomal recessive mutation in the obese (ob) gene encoding leptin [29]. ob/ob mice demonstrate markedly increased adiposity, hyperglycemia, and hyperinsulinemia.

Tumor growth in ob/ob mice was investigated after subcutaneous inoculation of murine melanoma B16 cells into female ob/ob and lean mice. In three different studies, primary tumor growth was unaffected, retarded, or enhanced in leptin-deficient mice compared to the lean controls, whereas tumor metastasis was suppressed in ob/ob mice. In contrast, intravenous inoculation of B16 cells in ob/ob mice was associated with an extensive formation of pulmonary metastasis. *In vitro*, serum obtained from ob/ob mice induces a mesenchymal phenotype and increases invasive potential of B16 cells which may explain a robust effect on pulmonary metastasis rather than primary tumor growth described earlier. A recent study also reported that the phenotype observed in ob/ob mice does not affect the development of carcinogen-induced skin papillomas and spontaneous p53-deficient malignancies (mostly lymphomas).

ob/ob mice, however, exhibited an increased incidence of preneoplastic lesions in the colon compared to the lean controls when treated with azoxymethane (AOM) and N-methyl-N-nitrosourea (NMU), two commonly used chemical carcinogens. When ob/ob mice were crossed with immunodeficient *scid* mice, subcutaneously inoculated HT-29 xenograft tumors grew more rapidly in obese than lean mice [30]. Reduction of circulating TNF-α levels resulted in suppressed IR signaling in tumor tissue and significantly alleviated tumor growth in ob/ob mice. When ob/ob mice were crossed with transgenic mice overexpressing TGF-α, a ligand for epidermal growth factor receptor, specifically in the mammary epithelium, a significantly reduced incidence of breast tumors was observed in leptin-deficient tumor-bearing mice.

Taken together, these data indicate that while ob/ob mice represent a valuable tool in obesity and diabetes research, it may not be an ideal model for cancer-associated studies since leptin may be required for tumor development. Indeed, recent data demonstrate that leptin signaling is required for the expansion of tumor-initiating cells, at least in the setting of hepatocellular carcinoma.

The $lepr^{db}/lepr^{db}$ (db/db) mice harbor another autosomal recessive mutation in the diabetes (db) gene which was eventually mapped to the leptin receptor (lepr or obr) gene locus. In contrast to leptin-deficient ob/ob mice, db/db animals have high circulating leptin levels resulting from leptin resistance. db/db mice also exhibit obesity, hyperglycemia, and hyperinsulinemia.

Zucker fatty (fa/fa) rats represent a commonly used rat model of genetically induced obesity. fa/fa rats harbor the autosomal recessive fatty (fa) mutation which, by analogy with the db allele, has also been mapped to the obr gene locus located on chromosome 5 in rats. Rats homozygous for the fa mutation display obesity, leptin and insulin resistance, hyperleptinemia and hyperinsulinemia.

LA/N-cp (corpulent) rat is another rodent model of genetically induced obesity that has been used (although less commonly) to study the impact of obesity, diabetes, and insulin resistance on tumor development. A homozygous recessive mutation in the corpulent gene (cp/cp) (also mapped to the obr gene locus) results in excess weight, hyperinsulinemia, and hyperlipidemia.

After intravenous inoculation of mouse melanoma B16 cells, pulmonary metastasis is enhanced in db/db mice. In addition, depletion of NK cells by an anti-asialo-GM1 antibody abrogated the enhanced metastasis in db/db mice.

To understand the impact of obesity on gastrointestinal tumors, chemically and genetically induced colon carcinogenesis was employed in leptin receptor-deficient rodent models. Growth of colorectal and gastric tumors was significantly enhanced in AOM- and NMU-treated db/db mice compared to the respective WT controls.

Food restriction in db/db mice resulted in normalized body weights and blood glucose levels; however, an increased number of premalignant lesions in colon was observed along with hyperinsulinemia and hyperleptinemia suggesting that either of these factors may be responsible for the increased tumor growth.

fa/fa rats are also more susceptible to chemically induced colon carcinogenesis when compared to lean controls, similar to db/db and ob/ob mice [31,32]. A moderate energy restriction that did not affect body weight resulted in the significantly reduced number of advanced crypt foci (ACF) in the colon of fa/fa rats. Similarly, pair feeding of fa/fa rats with lean control animals resulted in the reduced body weight and decreased ACF number in fa/fa rats. These dietary manipulations, however, did

not significantly affect hyperinsulinemia, thus suggesting that insulin may not be a major determinant of the tumor-promoting action of obesity on colon carcinogenesis in this specific model.

In addition, when *db/db* mice were crossed with *APC^1638N/+* mice, these animals had a higher number of tumors compared to *APC^1638N/+* mice. Tumors also had ectopic location (stomach and large intestine) in the double mutants (*APC^1638N/+/db/db*) but not in the *APC^1638N/+* mice [33]. *APC^1638N/+* mice have a mutation in the tumor suppressor *APC* gene resulting in the enhanced signaling through the Wnt/beta-catenin pathway. This model has a high clinical relevance as the majority (>90%) of patients with colorectal carcinoma harbor somatic mutations in genes encoding individual components of the Wnt/beta-catenin pathway.

The development of 7,12-dimethylbenz(a)anthracene (DMBA)-induced breast tumors is associated with a shorter tumor latency and a more aggressive phenotype in Zucker and corpulent female rats [32]. In contrast, the development of NMU-induced breast cancer is suppressed in female *fa/fa* rats [34,35]. This discrepancy has been attributed to the different mode of action of the two chemical carcinogens.

In genetically induced models of breast cancer, *db/db* mice also displayed attenuated tumor progression and/or metastasis when crossed with MMTV-PyMT (polyoma virus middle T antigen) or MMTV-TGF-α mice [36,37]. It is important to note that breast tumors in these models lack leptin receptors that apparently are critical for tumor development in this setting. This observation has been corroborated by a study with transplantable mammary tumors. When breast tumors induced by overexpression of Wnt transgene were transplanted into *db/db* mice, their growth was markedly accelerated in the setting of hyperleptinemia, whereas transplantation into leptin-deficient *ob/ob* mice resulted in the delayed tumor growth [38].

Taken together, the data obtained in the aforementioned models clearly indicate that obesity, diabetes and/or insulin resistance promote gastrointestinal carcinogenesis, although specific pathophysiologic mechanisms mediating this effect have not been clearly dissected. Studies aimed to elucidate the effect of obesity and diabetes on breast cancer and melanoma in leptin and/or leptin-receptor-deficient models should be interpreted with caution. A critical role of leptin signaling in normal and malignant mammary cells makes *ob* and *obr*-deficient models inappropriate to study breast carcinogenesis.

Diet-induced obesity (DIO) and cancer

Different types of high energy/high fat diet (HED or HFD), in which up to 60% calories are coming from fat, have been extensively employed in obesity and diabetes research. Animal models utilizing HFD and different tumor models are particularly helpful in understanding a relationship between obesity, insulin resistance, and tumor development. The major limitation of DIO models, similar to models of genetically induced obesity, is that in most cases they are unable to dissect a specific pathophysiologic mechanism mediating obesity-mediated

tumor progression, mostly in the setting of breast, prostate, and colon.

In most experimental models of breast cancer including NMU- and DMBA-induced models of chemically induced carcinogenesis as well as transgenic and implantation breast cancer models, DIO results in enhanced tumor development and progression. HFD promotes NMU-induced mammary carcinogenesis as demonstrated by shortened latency and increased multiplicity of tumors in Sprague-Dawley and Fischer 344 (F344) rats [39], whereas caloric restriction, physical exercise and dietary supplementation with fibers inhibit the stimulatory effect of HFD on NMU-induced tumor development [40,41]. DMBA-induced breast carcinogenesis is also enhanced in Sprague-Dawley rats fed a HFD [42], and ovariectomy further enhances this effect [43]. In C3H mice, obesity induced by a single injection of gold thioglucose, which induces necrosis in the ventromedial portion of hypothalamus, results in accelerated development of spontaneous mammary tumors , and HFD further enhances the incidence of mammary tumors in this model. Furthermore, while ovariectomized lean C3H female mice do not develop breast tumors, ovariectomized obese mice exhibit an increased tumor incidence compared to non-ovariectomized obese controls. Similar data were reported in the syngeneic Wnt-1 model of breast cancer. Ovariectomy inhibits growth of orthotopically inoculated estrogen-sensitive Wnt-1 cells in C57Bl/6 mice fed regular chow, whereas ovariectomized mice fed HFD further gain weight and display accelerated tumor growth, which is abrogated by calorie restriction and pharmacologic mTOR inhibition [44,45]. These data suggest that ovarian hormones have a different impact on tumor development in lean and obese animals. Obesity enhances tumors growth in the absence of ovarian hormones and this affect is mediated by the PI3K/Akt/mTOR pathway.

The stimulatory effect of DIO on tumor progression has been demonstrated in several transgenic mouse models of breast cancer. In the transgenic MMTV-v-Ha-ras and MMTV-TGF-α models, HFD increases the incidence and shortens the latency of breast tumors. HFD also significantly enhances growth of primary mammary tumors and pulmonary metastases when MMTV-driven polyoma virus middle T antigen (PyVmT) was introduced into M16i mice, which represent a model of polygenic obesity.

The effect of HFD on HER2/ErbB2-induced mammary tumorigenesis is not completely understood. HFD does not affect tumor latency, incidence, burden and metastasis in mice over-expressing wild-type Neu (mouse analogue of human HER2) in mammary epithelium but enhances tumor growth in MMTV-c-Neu mice that overexpress a constitutively active form of Neu [46,47].

In a xenograft LNCaP model, growth of subcutaneously inoculated tumor cells was significantly enhanced in nude mice fed a high calorie diet. This effect is accompanied by elevated insulin and IGF-I levels in the circulation, increased insulin receptor (IR) and IGF-I expression and enhanced Akt phosphorylation

in the tumor tissue [48]. However, tumor incidence is decreased in transgenic Hi-Myc and xenograft LNCaP models of prostate cancer when these mice are fed a low-fat diet. These animals display elevated IGFBP-1 levels in the circulation and reduced Akt phosphorylation in the tumor tissue, indicative of suppressed IR signaling [49,50]. Taken together, these data suggest a potential role of hyperinsulinemia and enhanced IR/IGF-IR signaling in the stimulatory effects of obesity on prostate tumor growth. In a model of AOM-induced colon carcinogenesis, HFD enhances ACF formation in F344 rats. HFD also increased the number of AOM-induced colon polyps in adiponectin and adiponectin receptor knockout mice compared to wild-type controls [51]. Administration of exogenous adiponectin inhibits growth of implanted tumors in mice fed a HFD, possibly through a direct regulation of cell proliferation, adhesion, invasion and anchorage-independent growth and modulation of several key tumorigenic signaling pathways (AMPK/mTOR, STAT3, VEGF, p21/p53/cyclin) [52]. However, transgenic overexpression of adiponectin fails to delay AOM-induced colon carcinogenesis. The results of these studies indicate that specific stimulatory effects of obesity on tumor growth can be mediated, at least in part, by hypoadiponectinemia, one of the hallmarks of obesity.

In the $APC^{1638+/-}$ mouse model of intestinal tumorigenesis, a Western-style diet containing high fat and phosphate but low calcium and vitamin D, enhances intestinal tumorigenesis. This diet also triggers adenoma formation in wild-type mice and significantly increases incidence, multiplicity and size of small and large intestinal adenomas in p27^{kip}-deficient mice. An exposure of p27^{kip}-null mice to HFD also results in the development of malignant tumors.

In the syngeneic colon carcinoma MC38 model, C57Bl/6 mice fed a HFD demonstrate increased tumor growth and metastasis. This effect is abolished in mice with genetically disrupted *igf1* gene in the liver resulting in chronic IGF-I deficiency [53]. Furthermore, the growth of implanted MC38 tumors in obese mice is enhanced by ovariectomy [54]. In ovariectomized animals fed a HFD, tumor growth was associated with insulin and leptin resistance as well as higher levels of pro-inflammatory proteins. In line with the aforementioned data on breast cancer, this study thus strongly supports the hypothesis that ovarian hormones have a modulatory effect on obesity-induced insulin resistance and inflammation, which may directly or indirectly influence colorectal tumor growth.

HFD also enhances growth of Lewis lung carcinoma (LLC) cells in C57Bl/6 mice [54]. In addition to HFD, high sucrose (HSD) and high cholesterol diets (HCD) are also capable of stimulating LLC growth and metastasis in recipient C57Bl/6 mice, but only HFD results in the development of obesity, insulin resistance, and hyperinsulinemia suggesting that factors other than insulin mediate tumor-stimulating effects of HSD and HCD.

HFD triggers the development of spontaneous hepatomas and enhances diethylnitrosamine-induced hepatocarcinogenesis in C3H mice and Sprague-Dawley rats, respectively. A diet enriched in fat and protein increases the incidence of DMBA-induced pancreatic cancer in Sprague-Dawley rats. In "Rockland strain" mice, HFD promotes benzpyrene-induced skin tumorigenesis. Rapid body weight gain also increases the risk of UV radiation-induced skin carcinogenesis in SKH-1 hairless mice.

Taken together, these data indicate a stimulatory effect of DIO on tumor growth. However, most of the studies described earlier do not dissect a specific pathophysiologic mechanism mediating this effect although several lines of evidence indicate that IR/IGF-IR and/or adiponectin signaling may play a role in this process.

Non-obese models of type 2 diabetes and cancer

A-ZIP/F-1 or fatless mouse represents a transgenic mouse model of lipoatrophic diabetes which was employed to dissect effects of body adiposity and diabetes on tumor growth. Skin and breast carcinogenesis is remarkably enhanced in A-ZIP/F-1 mice compared to the respective controls. These findings indicate that in the absence of fat tissue diabetes per se has a direct stimulatory effect on malignant transformation and tumor growth. The results of this study, however, should be interpreted with caution because (i) lipoatrophic form of T2DM is rare in humans, (ii) A-ZIP/F-1 mice have severely impaired mammary gland development, and (iii) the spectrum of metabolic abnormalities in A-ZIP/F-1 mice is very diverse and includes hyperinsulinemia, severe hyperglycemia, hyperlipidemia, elevated levels of circulating IGF-I and proinflammatory cytokines, and each of these factors may be capable of enhancing tumor growth. In addition, tumor tissue in A-ZIP mice has increased levels of phosphorylated ERK1/2 and Akt, whereas IR phosphorylation is attenuated suggesting that other factors rather than the IR are responsible for enhanced signaling though the PI3K and MAPK pathways in this model.

MKR mouse represents a unique transgenic model of T2DM. In this model, a mutant IGF-IR (IGF-IR^{K1003R}) is exclusively overexpressed in the skeletal muscle under the control of a muscle creatine kinase promoter. The overexpression results in the abrogation of insulin and IGF-I/II signaling due to the formation of hybrids between dominant-negative IGF-IR^{K1003R} and endogenous insulin and IGF-I receptors. MKR females display a mild diabetic phenotype; they develop severe insulin resistance and hyperinsulinemia in the setting of moderately reduced body adiposity and mild dysglycemia and hyperlipidemia [55]. This model is particularly useful in understanding the effects of hyperinsulinemia and insulin resistance on tumor growth. MKR female mice demonstrate a more aggressive phenotype and enhanced tumor growth in transgenic MMTV-PyVmT and syngeneic Met-1 and MCNeuA models of breast cancer [55]. In addition, MKR mice display markedly enhanced pulmonary metastasis after orthtopic and intravenous inoculation of Mvt-1 cells and in transgenic doxycycline-inducible MMTV-rtTA/tetO-NeuNT model of breast cancer [56]. Tumor tissue extracted from MKR mice displays enhanced phosphorylation of the IR/IGF-IR, Akt,

S6 ribosomal protein and upregulation of c-myc expression suggesting a direct effect of hyperinsulinemia on the IR and/or the IGF-IR with subsequent activation of the PI3K/Akt/mTOR pathway and c-myc-driven expression in tumor cells [55 – 57]. Furthermore, pharmacologic correction of insulin resistance and hyperinsulinemia by insulin-sensitizing agent and pharmacologic blockade of insulin and IGF-I receptors by BMS-536924 abrogate tumor-promoting effects of hyperinsulinemia in MKR mice [55]. In addition, administration of the PI3K/Akt/mTOR pathway by rapamycin, NVP-BEZ235 and NVP-BKM-120, small molecule inhibitors which block the pathway at different levels, is also capable of preventing accelerated tumor growth in MKR mice [57,58]. Collectively, these data corroborate a key pathophysiologic role that insulin and its cognate receptor play in the setting of insulin resistance and identify downstream signaling molecules that mediate this effect.

Conclusions and future directions

While there is compelling epidemiologic evidence of the association of diabetes and cancer risk and experimental evidence is being obtained regarding the potential factors that may be causative, much more research on this topic is to be encouraged. More studies are required to show the relationship across various ethnic and racial groups. Additional data are necessary to definitively establish which cancers are involved. Finally, both animal and human studies will be necessary to fully determine the major causal factors to then proceed with preventative and therapeutic options.

Diabetes and sleep apnea

Abd A. Tahrani

Centre of Endocrinology, Diabetes and Metabolism (CEDAM), School of Clinical and Experimental Medicine, University of Birmingham, Birmingham, UK

Key points

- Obstructive sleep apnea (OSA) is common and associated with increased risk of dysglycemia, type 2 diabetes, hypertension, cardiovascular disease, and mortality.
- Patients with type 2 diabetes and insulin resistance are at increased risk of developing OSA.
- OSA is associated with activation of the hypothalamic pituitary adrenal axis, adipokine changes, autonomic dysfunction, increased inflammation and oxidative stress, and endothelial dysfunction which might explain the association between OSA and dysglycemia.
- CPAP (continuous positive airway pressure) treatment improves many of the molecular and hormonal consequences of OSA and has a beneficial impact on OSA comorbidities, but the impact of CPAP in patients with type 2 diabetes remains unclear.

Introduction

Obesity is a global epidemic that has far-reaching economic and public health implications [1]. Excess body weight is associated with multiple comorbidities including type 2 diabetes (T2DM), hypertension, obstructive sleep apnea (OSA), and cardiovascular disease (CVD) [2]. Dysglycemia and OSA share common risk factors such as age and obesity; hence it is not surprising that OSA and glycemic abnormalities often coexist.

Despite the close association between OSA and dysglycemia, the direction of this association and whether obesity modulates the association remain unclear. The interaction between multiple genetic and environmental factors gives rise to a heterogeneous and progressive condition with variable degrees of insulin resistance (IR) and pancreatic β-cell dysfunction [3]. When β cells are no longer able to secrete sufficient insulin to overcome IR, impaired glucose tolerance (IGT) progresses to T2DM [3]. OSA is associated with different factors that alter IR and β-cell function suggesting that OSA can result in glycemic abnormalities. On the other hand, dysglycemia and its association with inflammation and autonomic dysfunction can lead to or worsen pre-existing sleep apnea [4].

An increasing number of human and animal studies have expanded our understanding of the association between OSA and dysglycemia and how each condition modulates the metabolic impacts of the other [5]. In this chapter we aim to review the evidence for the association between OSA and dysglycemia, to explore the underlying mechanisms and to assess the metabolic impacts of OSA in the presence of dysglycemia and vice versa. The mainstay of this chapter will focus on OSA, rather than central sleep apnea (CSA), as it is the most common type of sleep apnea and the one that is closely related to obesity and T2DM. We will, however, highlight some important issues in relation to CSA when needed.

Definitions

Sleep apnea can be either central or obstructive. OSA is a common medical disorder that is characterized by instability of the upper airway during sleep, which results in markedly reduced (hypopnea) or absent (apnea) airflow at the nose or mouth [6]. These apnea/hypopnea episodes are usually accompanied with oxygen desaturations and micro arousals that cause sleep fragmentation and reduction in slow wave and rapid eye movement (REM) sleep [6]. The American Academy of Sleep Medicine (AASM) 2007 guideline has defined sleep events apnea as cessation or $\geq$90% reduction in airflow for a period of $\geq$10 seconds and hypopnea as $\geq$30% reduction in airflow for $\geq$10 seconds associated with $\geq$4% drop in oxygen saturations; an alternative definition of hypopnea based on $\geq$50% reduction in airflow with $\geq$3% drop in oxygen saturations can also be used [7]. The updated AASM 2012 guidelines defined hypopnea in adults as $\geq$30% drop of air flow of pre-event baseline for $\geq$10 seconds in association with either $\geq$3% arterial oxygen desaturation or an arousal [8]. Apneas are classified into obstructive or central
Figure 22.1 An example of apnea (red), hypopneas (pink), and desaturations (green) in a patient with OSA and T2DM. Note the the presence of thoracic and abdominal movements indicating the presence of obstructive rather than central sleep apnea. (For a color version of this figure, please see the color plate section.)

based on the presence or absence of respiratory/abdominal efforts. An example of apneas and hypopneas can be found in Figure 22.1.

The apnea-hypopnea index (AHI) is the average number of apnea and hypopnea episodes per hour during sleep and is a marker of the severity of OSA [6]. An AHI of ≥5 events per hour is consistent with the diagnosis of OSA [9]. OSA can be classified to mild, moderate, and severe based on AHI 5 to <15, 15 to <30, and ≥30 events per hour. The respiratory disturbance index (RDI) is another OSA measure that includes the AHI in addition to respiratory effort-related arousal, which is defined as a sequence of breaths characterized by increasing respiratory effort leading to an arousal from sleep, but which does not meet criteria for an apnea or hypopnea [6]. Another measure of OSA is the oxygen desaturation index (ODI), which is the average number of oxygen desaturations per hour during sleep.

OSA epidemiology and risk factors

The prevalence of OSA varies considerably between studies, mainly due to differences in the population studied, study designs, and the method and criteria used to diagnose OSA. A prevalence of 4% in men and 2% in women [6] has traditionally been quoted in many populations. The prevalence from three well-conducted studies with similar design from Wisconsin, Pennsylvania, and Spain showed an OSA prevalence of 17–26%

in men and 9–28% in women and a prevalence of 9–14% and 2–7% for men and women with moderate to severe OSA [10]. These studies used a two-stage sampling design which allows some degree of estimate of the "self-selection" bias which is usually a significant problem in OSA studies.

OSA prevalence is affected by many risk factors such as obesity, age, ethnicity, and gender. The large majority of epidemiologic OSA studies took place in Western societies (particularly in the USA) and included mainly white Caucasians; hence data about the prevalence in other ethnicities is rather limited. In African Americans, the available results are conflicting. While some studies showed a higher adjusted OSA prevalence in Afro-Caribbeans (increased twofold) [10], others did not show such a difference [11]. Chinese have a high OSA prevalence (8.8% in men and 3.7% in women) despite being less obese than white Europeans [12,13]. This highlights the importance of factors other than obesity (such as the anatomy of upper airways) in the development of OSA. Chinese were shown to have more crowded upper airways with higher Mallampati score and shorter thyromental distance [14]. Data regarding the prevalence of OSA in South Asians are also limited. In a semi-urban population in Delhi, the OSA prevalence was 3.7% [15], this rose to 9.3% in middle-aged urban Indians [16], and 19.5% in middle-aged urban men [17].

The impact of gender on OSA status has been well recognized; men have two to three times increased risk of OSA compared to women [10]. The exact mechanisms behind the

gender differences in OSA prevalence are not clear but several possible factors have been proposed. Sex hormones have been implicated, since men receiving testosterone replacement are at higher risk of OSA and the prevalence of OSA in post-menopausal women is higher than in premenopausal women. Hormone-replacement therapy also reduces the risk of OSA in postmenopausal women [18]. In addition, hyperandrogenemia was associated with higher risk of OSA and oral contraceptives were associated with lower OSA risk in women with polycystic ovarian syndrome [19]. Differences in upper airway size and ventilator control between men and women have also been implicated but the results are conflicting [20].

Several studies have shown that the prevalence of OSA increases with age [18]. In men, OSA (AHI ≥10 events per hour) was present in 3.2%, 11.3%, and 18.1% of the 20–44, 45–64, and 61–100-year-old age groups, respectively [21]. In another study from Spain, the prevalence of any OSA was three times higher and the prevalence of moderate to severe OSA was four times higher in older patients (>70 years old) compared to middle-aged participants [10]. On the other hand, in the Sleep Heart Health Study, OSA prevalence increased with age but reached a plateau at the age of 65 years, which may be related to survival effect [11]. The relationship with age seems to be due to changes in pharyngeal anatomy and upper airway collapsibility [18].

Excess body weight is an essential risk factor for OSA, although not all OSA patients are obese or overweight. In the Wisconsin Sleep Cohort Study, each increase in BMI by one standard deviation, resulted in a fourfold increase in OSA prevalence [22]. Several other studies have shown the strong link between OSA and excess body weight [18]. Prospective studies showed that weight gain is associated with the development of or worsening pre-existing OSA [23,24]. This was further supported by a randomized controlled trial which showed that weight loss (vital life style modifications or surgical intervention) improve/cure OSA [25,26]. The mechanisms that link obesity to OSA are not entirely clear but several mechanisms have been proposed; weight gain can alter normal upper airway mechanics during sleep by increased parapharyngeal fat deposition resulting in a smaller upper airway, altering the neural compensatory mechanisms that maintain airway patency, reducing the functional residual capacity with a resultant decrease in the stabilizing caudal traction on the upper airway and affecting the chemosensitivity to O_2 and CO_2 which reduces ventilator drive [27].

There are several other predisposing risk factors to OSA such as current smoking, excess alcohol intake, and genetic factors [10,18].

OSA pathophysiology

OSA is a very complex disorder, and although obesity and fat deposition around the neck plays an important role, there are many other important players that contribute to the development of this condition.

The human upper airway is a unique multipurpose structure involved in performing a variety of tasks such as speech, swallowing, and the passage of air for breathing [28]. The airway, therefore, is composed of numerous muscles and soft tissue but lacks rigid or bony support [28]. Most notably, it contains a collapsible portion that extends from the hard palate to the larynx which allows the upper airway to change shape and momentarily for speech and swallowing during wakefulness; but this feature also provides the opportunity for collapse at inopportune times such as during sleep [28]. Several imaging-based studies showed that patients with OSA have a smaller upper airway during wakefulness and anesthesia, resulting in an airway that is more prone to collapse [28]. The upper airway muscles (genioglossus) activity is also increased in OSA patients compared to age- and obesity-matched healthy controls [29], suggesting that these muscles are compensating for an underlying defect in the anatomy of the upper airway in patients with OSA [28]. This muscle hyperactivity is resolved in CPAP-treated patients [30]. Sleep onset is associated with greater reductions in upper airway muscles tone in OSA patients, which explains the occurrence of apnea/hypopnea episodes at sleep onset and during REM sleep [28]. This reduction in upper airway muscle tone during sleep seems to result from a central lack of drive and local inhibitory reflexes that respond to changes in pressure in the upper airways [28]. Several studies have also shown that changes in lung volume affect upper airway muscles activity [28]. Other abnormalities described in OSA include irregularities in ventilatory control and stability, changes in chemosensitivity to CO_2, and higher arousal thresholds [28].

OSA clinical features and diagnosis

Good history and examination are still an essential part of the assessment of patients with OSA despite the fact that several reports have shown the limited value of symptoms in predicting OSA (in one report, only one third of patients would have been identified clinically) [31]. Snoring is the most common symptom of OSA and it occurs in 95% of patients [6]. Snoring, however, has a poor predictive value due to the high prevalence of snoring and the fact that many snorers do not have OSA [6]. Nonetheless, lack of snoring almost rules out OSA since only 6% of OSA patients (or their partners) have not reported snoring [6]. Witnessed apneas are another important symptom that is usually reported by the partner. However, witnessed apneas do not correlate with disease severity and up to 6% of the "normal" population could have witnessed apneas without OSA [6]. Other nocturnal symptoms such as choking (which is possibly a "proper" rather than a "micro" arousal to terminate apnea), insomnia, nocturia, and diaphoresis have been reported [6]. Daytime symptoms include excessive

daytime sleepiness, fatigue, morning headache, and autonomic symptoms [6].

The gold standard to diagnose OSA is polysomnography that typically includes the recording of 12 channels such as EEG, electro-oculogram (EOG), electromyogram (EMG), oronasal airflow, chest wall effort, abdominal effort, body position, snore microphone, ECG, and oxyhemoglobin saturation [6]. The main problem with polysomnography is that it is time consuming and expensive. Portable home-based respiratory devices are another alternative [6]. The main advantages are that they are less resourceful but they are associated with higher failure/loss of lead rate compared to polysomnography [6]. Pulse oximetry is another good way to diagnose OSA, it cannot, however, differentiate between obstructive and central apneas and it has a wide range of sensitivity (31–98%) and specificity (41–100%). The AASM recommends use of a Type III device as a minimum [6].

OSA and glucose metabolism

OSA and dysglycemia have similar risk factors (namely obesity) and hence it is not surprising that these conditions co-exist. However, not all obese patients have both conditions and many patients have one and not the other. Hence, understanding this association and the mechanisms that underpin this relationship is important to understand the pathogenesis of OSA and T2DM. There are many studies that have examined the association between snoring, as a surrogate marker of OSA, and different aspects of glucose metabolism [32]; here, however, we will mainly focus on studies that validated the presence and severity of OSA using more accurate methods.

OSA and prediabetes
OSA has been associated with components of the metabolic syndrome and with IR independent of obesity [33]. Some studies reported that abnormal glycemia could occur in as many as 79% of patients with OSA [34]. In a cross-sectional analysis in a subset of the Sleep Heart Health Study, relative to those with RDI < 5, individuals with mild and moderate to severe OSA had adjusted OR of 1.27 (95% CI 0.98–1.64) and 1.46 (95% CI 1.09 –1.97), respectively for fasting glucose intolerance [35]. Sleep-related hypoxemia was also associated with glucose intolerance independently of age, gender, BMI, and waist circumference [35]. In another study that included 150 men not known to have diabetes, an AHI ≥5 was associated with an increased risk of IGT or DM (based on OGTT) (OR: 2.15; 95% CI 1.05–4.38) following adjustment for BMI and body fat (as measured by hydrodensitometry) [36]. For each 4% decrease in oxygen saturation, the OR of worsening glucose tolerance was 1.99 (95% CI 1.11–3.56) after adjusting for percent body fat, BMI, and AHI [36]. Similarly, in a cross-sectional analysis of 2588 participants (aged 52–96 years; 46% men), the OSA group (RDI ≥10) had higher adjusted OR of 1.3 (95%

CI 1.1–1.6) for IFG (impaired fasting glucose), 1.2 (1.0–1.4) for IGT, 1.4 (1.1–2.7) for IFG plus IGT, and 1.7 (1.1–2.7) for occult diabetes compared to those without OSA [37]. In overweight/obese individuals, FPG and the 2-h OGTT glucose values were significantly higher in patients with vs. without OSA while there was no such difference in normal-weight subjects [37]. In the same study, the prevalence of abnormal glycemia was significantly higher in normal (679 subjects) and overweight/obese (1909 subjects) individuals with OSA compared to those without (no OSA vs. OSA: 17.6% vs. 25.5%, $p = 0.03$ and 36.9% vs. 43%, $p = 0.02$ for IFG; 5.1% vs. 9.3%, $p = 0.06$ and 13.6% vs. 17.3%, $p = 0.05$ for combined IFG and IGT; 5.7% vs. 9.3%, $p = 0.09$ and 9.3% vs. 13.2%, $p = 0.01$ for normal and overweight/obese subjects, respectively] [37]. More recently, the higher AHI and lower nocturnal hypoxemia were shown to be associated with higher HbA1c in patients without diabetes despite adjustment for a wide range of confounders in a cross-sectional study [38].

OSA and insulin resistance
Several studies examined the association between OSA and IR (Table 22.1). The majority of these studies were conducted in white Caucasians, but some included patients of other racial groups and ethnicities. The major difficulty in examining the association between OSA and IR is teasing out the impact of OSA from that of obesity. Most studies showed an association between OSA and IR, but some did not (Table 22.1). Studies that did not show such a relationship included fewer participants and potentially were underpowered.

Interestingly, a small recent study suggests that excessive daytime sleepiness may be, in part, responsible for the IR in patients with OSA [39]. Barcelo et al. studied 44 patients with OSA (22 with and 22 without excessive daytime sleepiness) matched for age, BMI and AHI, and 23 healthy controls [39]. Patients with excessive daytime sleepiness (assessed by the Epworth Sleepiness Scale and the Multiple Sleep Latency Test) had higher HOMA-IR compared with OSA patients without excessive daytime sleepiness or healthy controls [39]. The difference in HOMA-IR between OSA patients without excessive daytime sleepiness and healthy controls was not significant [39]. Glucose levels were significantly higher in patients with OSA and excessive daytime sleepiness compared to those with OSA without excessive daytime sleepiness and healthy controls [39]. In support for the association between excessive daytime sleepiness and IR, CPAP treatment in the same study reduced the HOMA-IR and increased IGF-1 levels in patients with excessive daytime sleepiness, but did not modify any of these variables in patients without excessive daytime sleepiness [39]. This impact of excessive daytime sleepiness may explain in part some of the variation in the association between OSA and IR observed in cross-sectional studies. Recent studies tried to exclude the impact of obesity on IR by examining healthy lean men and found that OSA was associated with IR despite the lack of obesity (Table 22.1) [40,41].

Table 22.1 Summary of studies that examined the association between OSA and insulin resistance (IR)

Study/ year	Study population	Sample size	OSA assessment	IR assessment	Confounders assessed	Results	Association
Tiihonen et al. [43] 1993	Suspected OSA	18	Oximetry	IR index during OGTT	Age, BMI	IR independently associated with ODI after adjustment	+
Strohl et al. [44] 1994	Suspected OSA, all men, mean age 47 years	261	PSG	Fasting insulin	BMI	IR correlated with AHI independent of BMI	+
Davies et al. [45] 1994	Confirmed OSA and control for snorers	15 OSA/ 18 control	PSG	Fasting insulin	Matched for age, sex, BMI, smoking, and alcohol	No difference in IR between groups	–
Grunstein et al. [46] 1995	The Swedish Obese Subjects cohort	3034	Questionnaire	Fasting insulin	BMI, visceral fat, age	IR higher in patients with high risk for OSA after adjustment	+
Stoohs et al. [47] 1996	Healthy individuals (34 women) with a mean age of 44.3 years and a mean BMI of 27.1	50	Validated sleep apnea recorder	Insulin suppression test with somatostatin analogue	BMI	IR was higher in individuals with ODI $\geq 10\,h^{-1}$ but the difference disappeared after adjusting for BMI	–
Saarelainen et al. [48] 1997	Randomly selected OSA patients from sleep clinic, no controls	10	PSG	Euglycemic hyperinsulinemic clamp	Age, BMI	No association between IR and OSA	–
Ip et al. [49] 2000	OSA patients and controls from a sleep clinic in Hong Kong	30/30	PSG	Fasting insulin	Matched for BMI, age, sex, menopausal status	OSA correlated with IR after adjustment	+
Vgontzas et al. [50] 2000	Obese men with OSA and control groups	37	PSG	Fasting insulin	OSA were age and BMI matched to nonapneic individuals and age-matched lean men	OSA patients were more insulin resistant compared to nonapneic patients. However, visceral fat was higher in patients with OSA despite similar BMI to those without OSA	+
Elmasry et al. [51] 2001	Hypertensive men	116	PSG	Fasting insulin	Waist:hip ratio, age	OSA was associated with IR after adjustment	+
Ip et al. [52] 2001	Consecutive Chinese subjects (197 men) from the Hong Kong sleep clinic	270	PSG	HOMA-IR	BMI, age	AHI and minimum oxygen saturation independently associated IR; this association was seen in obese and nonobese individuals. Each additional AHI unit per sleep hour increased the fasting insulin level and HOMA-IR by about 0.5%	+

Study	Population	N	Validated sleep recorder	Euglycemic hyperinsulinemic clamp	Adjustment	Findings	Result
Manzella et al. [53] 2002	OSA patients, mean BMI 30.9 kg m^{-2}	20		Euglycemic hyperinsulinemic clamp	Age, sex, BMI, leptin, PCO2	AHI correlated with insulin-mediated glucose uptake ($r=-0.73$; $p<0.001$), remained significant after adjustment	+
Punjabi et al. [36] 2002	Community sample, all men, mean BMI 30.5 kg m^{-2}	151	PSG	HOMA-IR	BMI, percent body fat	increasing AHI was associated with worsening insulin resistance independent of obesity	+
Meslier et al. [54] 2003	All men suspected with OSA	595	PSG	HOMA-IR	Age, BMI	Insulin sensitivity decreases as OSA severity increased	+
Tassone et al. [55] 2003	Obese OSA patients, mean BMI 38.6, mean AHI 40.5 compared to weight-matched nonapneic controls	30/27	PSG	ISI	Age, BMI, waist:hip ratio, sex	ISI was lower in OSA patients	+
Barcelo et al. [56] 2004	OSA and control	65	PSG	HOMA-IR	Age and BMI	No association	+
Punjabi et al. [35] 2004	Community sample	2656	PSG	HOMA-IR	Age, sex, ethnicity, smoking, BMI, waist circumference, and sleep duration	Moderate to severe OSA was associated with IR	+
Makino et al. [57] 2006	Japanese patients with OSA	213	PSG	HOMA-IR	Age, BMI	AHI independently associated with IR after adjustment	+
Gruber et al. [58] 2006	Suspected OSA	79	PSG	HOMA-IR	Age, BMI, smoking history	OSA was associated with IR but not after adjustment	−
McArdle et al. [59] 2007	Moderate to severe OSA patients with controls	42	PSG	HOMA-IR	Controls matched for age, BMI, and smoking	OSA associated with higher HOMA-IR, remained significant after adjustment	+
Sharma et al. [60] 2007	OSA patients with obese and nonobese controls	40/40/40	PSG	HOMA-IR	BMI	No difference in IR across groups	−
Onat et al. [61] 2007	Turkish population	1946	symptoms	HOMA-IR	Age, BMI, WHR	No association	−
Kapsimalis et al. [62] 2008	Suspected OSA	67	PSG	HOMA-IR	BMI, WHR	No association	−
Theorell-Haglow et al. [63] 2008	Population-based, all women	400	PSG	ISI	Age, WHR, physical activity, smoking, alcohol	Nocturnal minimal saturation was independently associated with decreased ISI after adjustment	+

(*continued overleaf*)

Table 22.1 (*continued*)

Study/ year	Study population	Sample size	OSA assessment	IR assessment	Confounders assessed	Results	Association
Tkacova et al. [64] 2008	Suspected OSA	98	PSG	HOMA-IR	Age, BMI, sex	OSA associated with IR	+
Punjabi & Beamer [65] 2009	Suspected OSA	118	PSG	Frequent sampling intravenous glucose tolerance test	Age, sex, race, BMI, body fat	OSA associated with IR. IR increases in a stepwise manner across OSA severity categories	+
Polotsky et al. [66] 2009	Consecutive individuals with BMI > 40	90	PSG	HOMA-IR	BMI, waist circumference	Oxygen desaturation greater than 4.6% was associated with a 1.5-fold increase in IR	+
Bhushan et al. [67] 2010	Obese South Asians with OSA and matched control	121/119	PSG	Fasting insulin	Matched for age, BMI, and % body fat	Fasting insulin was associated with OSA	+
Togeiro et al. [68] 2012	Community sample from Brazil	1042	PSG	HOMA-IR	Age, sex, abdominal obesity, total sleep time	Moderate to severe OSA and time of oxygen saturation <90% were independently associated with impaired fasting glucose, elevated triglycerides, and HOMA-IR	+
Pamidi et al. [40] 2012	Healthy men, aged 23 years and BMI 22.6 kg m^{-2}	52	PSG	Matsuda index and insulin AUC during OGTT	Groups matched for age, BMI, family history of diabetes, exercise	Patients with OSA had lower insulin sensitivity and higher insulin secretion than the control subjects, despite comparable glucose levels	+
Lin et al. [41] 2012	Individuals with and without OSA, aged 47.5 years, BMI 22.7. China	113/45	PSG	HOMA-IR	OSA and controls were matched for age, BMI, gender and waist circumference	AHI correlated positively with HOMA-IR	+

ISI, insulin sensitivity index; PSG, polysomnography.

Unlike previous cross-sectional studies, OSA, AHI, ODI, and minimal oxygen saturations were independently associated with IR development over an 11-year follow-up period after adjustment for age, baseline BMI, hypertension, BMI change over follow-up, and CPAP treatment [42].

In the light of the association between OSA and IR, there was a wide interest in the impact of CPAP treatment on IR. Unfortunately the impact of CPAP on IR is not clear. While some studies showed that CPAP treatment lowered IR [69,70], others did not [45,49,71–73]. CPAP treatment varied in these studies from 1 night to 3 years. The lack of a positive effect of CPAP on IR may be the result of several methodological limitations such as the lack of a control group, short duration of CPAP treatment, and small sample sizes. However, it is possible that the impact of long-standing OSA on IR is irreversible. Two recent meta-analyses showed that CPAP treatment was associated with a reduction in HOMA-IR [74,75], although this benefit may occur only in those using CPAP >4 h per night [76]. An in-depth review on the impact of CPAP on glucose metabolism can be found in [77].

OSA and β-cell function

While the impact of OSA in IR has been studied extensively, the impact of OSA on β-cell function has received little attention, despite being an essential part of the pathogenesis of T2DM and prediabetes. A small number of animal studies showed that intermittent hypoxia increases β-cell death, and results in β-cell dysfunction, although the intermittent hypoxia used in this study is far greater than that which occurs in humans with OSA [78]. One study in humans examined 118 patients without diabetes using the modified frequent sampling intravenous glucose tolerance test and found that the disposition index, a measure of β-cell function, was also reduced in patients with moderate to severe sleep-disordered breathing [65]. Similarly, a more recent study in patients with T2DM showed that patients with OSA had lower insulin secretion reserve than those without OSA [79], but there was no adjustment for adiposity differences between groups

Mechanisms underpinning the relationship between OSA and dysglycemia

Despite the strong association between OSA and dysglycemia, the underlying mechanisms are not clear. There are, however, several possible mechanisms that link OSA to dysglycemia, IR, and β-cell dysfunction, such as changes in sleep architecture, sympathetic overactivation, increased inflammatory cytokines, hormonal changes, increased oxidative stress, and the development of nonalcoholic fatty liver disease (NAFLD) (Figure 22.2).

Intermittent hypoxia is an important component of OSA and may contribute to much of its pathologic consequences. Intermittent hypoxia for as little as 5 hours in healthy volunteers can reduce insulin sensitivity without compensatory increase in insulin secretion, suggesting an impact on β-cell function as well [80]. Intermittent hypoxia is associated with increased hypoxia-inducible factor-1 (HIF-1) which occurs either secondary to hypoxia itself [81] or to oxidative stress [82]. HIF-1 upregulates sterol regulatory element-binding protein (SREBP)-1 [83], which is associated with increased lipid biosynthesis and insulin resistance [84]. HIF is also involved in systemic inflammation [85]. Interestingly, in mice with partial deficiency of HIF-1, intermittent hypoxia does not result in IR [3,83].

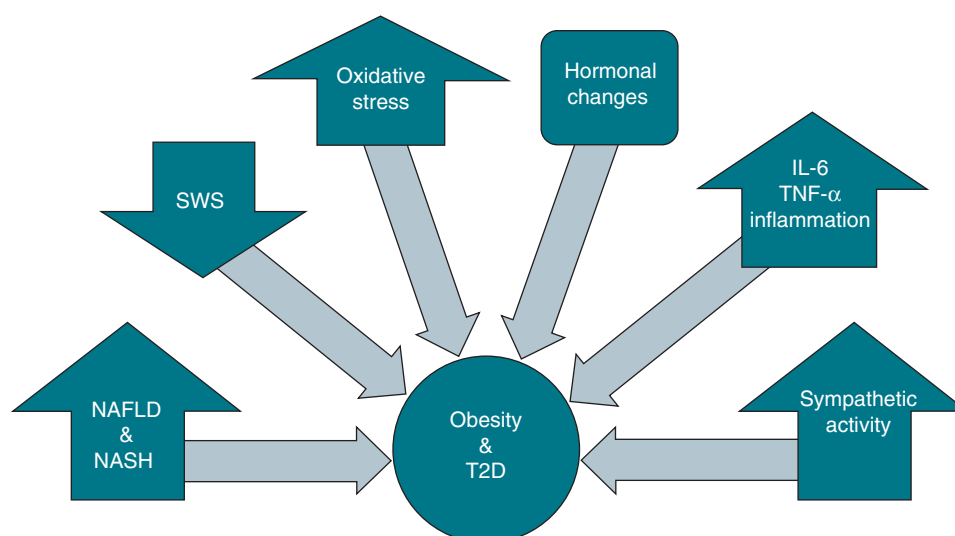
In addition to intermittent hypoxia, OSA is associated with changes in sleep architecture such as reduction in slow wave sleep and sleep quality resulting in excessive daytime sleepiness. These changes in sleep architecture and quality have


Figure 22.2 Possible mechanistic links between OSA and glucose metabolism. SWS, slow-wave sleep; NALFD, nonalcoholic fatty liver disease; NASH, nonalcoholic steatohepatitis.

been associated with a reduction in insulin sensitivity and dysglycemia [86].

OSA is associated with many hormonal changes that can affect glucose metabolism. These include activation of the hypothalamic pituitary adrenal (HPA) axis and suppression of the GH axis and IGF-1; some of which can be reversed with CPAP treatment [87,88]. Gherlin has been shown to be higher in patients with OSA, which is reduced by CPAP treatment [89]. Catecholamines are also elevated in patients with OSA and are lowered by CPAP [90].

OSA is also associated with changes in adipokines. Adiponectin levels correlate negatively with the OSA severity independent of age, BMI, and visceral fat volume [91]. Several other studies showed lower adiponectin levels in OSA patients, although short CPAP treatment did not seem to reverse this trend [92,93]. Inversely to adiponectin, leptin levels were shown to be higher in obese subjects with OSA compared to age and BMI-matched obese subjects without OSA ($p < 0.05$) [50]. There are several studies that similarly showed increased leptin levels in patients with OSA [49].

Sympathetic overactivation plays an important role in the regulation of glucose and fat metabolism and the development of T2DM [94]. OSA is associated with increased sympathetic activity [92]. It is likely that both the recurrent hypoxia [95] and recurrent arousals [96] contribute to the activation of the sympathetic system. OSA is also associated with elevated inflammatory cytokines such as IL-6, TNF-α, and NF-κB [92].

OSA may also be a risk factor for the developing of histologically proven nonalcoholic fatty liver disease (NAFLD) and for progressing to NASH [66,97]. Nocturnal desaturations were found to be associated with hepatic inflammation, hepatocyte ballooning, and liver fibrosis [66]. Another study also found that subjects with histologic NASH had significantly lower desaturation, lower mean nocturnal oxygen saturation, and higher AHI compared with non-NASH controls [97]. A randomized controlled trial showed that four weeks of CPAP had no impact on liver enzymes in patients with moderate to severe OSA [98]; it must be noted, however, that liver enzymes are not a sensitive measure of NAFLD/NASH.

Recurrent hypoxia and mitochondrial dysfunction in OSA result in the formation of reactive oxygen species (ROS) which leads to cellular and DNA damage and oxidative stress [99]. Many studies support OSA as a cause of oxidative stress [92]. Repetitive episodes of re-oxygenation following hypoxia, as seen in OSA, simulate ischemia–reperfusion injury which results in the generation of ROS [100]. ROS levels have been shown to be 2–3 times higher in patients with OSA compared to healthy controls [99]. In addition, multiple studies have shown increased oxidized lipids, DNA, and carbohydrates in patients with OSA and animals exposed to intermittent hypoxia [99].

All the afore-mentioned mechanisms can impact on IR and/or β-cell function resulting in impaired glucose metabolism and eventually T2DM.

OSA and T2DM

OSA and incident T2DM

Several studies have examined whether having OSA increases the individual's risk of developing T2DM, in particular whether obesity is a major risk factor for both conditions and whether OSA has been associated with IR and prediabetes as described earlier. Several cross-sectional studies found a higher prevalence of T2DM in patients with OSA despite adjusting for confounders, particularly age and obesity; these studies are reviewed in [101]. Whether OSA is a predictor of T2DM has been examined in a small number of longitudinal studies that used a variety of methods to diagnose OSA (from symptoms to polysomnography), and to diagnose T2DM (from self-reported to OGTT); these studies are summarized in Table 22.2. A recent meta-analysis of studies that used objective measures to diagnose OSA found that moderate to severe OSA was associated with increased risk of developing T2DM (RR 1.63; 95% CI 1.09–2.45) [102].

OSA prevalence in T2DM

Given the high prevalence of glycemic abnormalities in patients with OSA, it is not surprising that OSA is very common in patients with T2DM. However, there is significant variation in OSA prevalence between studies due to differences in population characteristics (primary vs. secondary care, long vs. short diabetes duration, ethnicity, obesity, and so on), and differences in the methods and criteria used to diagnose OSA. These studies are summarized in Table 22.3.

As a result of the high prevalence of OSA in patients with T2DM, the International Diabetes Federation (IDF) recommended screening for OSA in this high-risk population [108], although appropriate validated screening methods in patients with T2DM are still lacking.

OSA and glycemic control in T2DM

Since OSA is associated with IR and possibly β-cell dysfunction, and increased inflammation and oxidative stress (see later for more details), it is logical to hypothesize that OSA leads to worsening glycemic control in patients with T2DM. The main difficulty in OSA-related research is to differentiate the impact of OSA from that of obesity. A small number of studies assessed this issue, and they demonstrated that OSA and OSA severity are associated with poorer glycemic control (both HbA1c and fasting plasma glucose) and glycemic variability after multivariable adjustments for several confounders, such as age, sex, race, BMI, number of diabetes medications, level of exercise, years of diabetes and total sleep time in some studies [117,120–123]. These studies were relatively small ($n = 31$–92). The adjusted mean increase in HbA1c between patients with and without OSA varied from 0.7% to 3.69% depending on the OSA severity. One study, however, did not show an association between OSA and glycemic control [112]; but in this study only 22% of participants had full polysomnography and the duration of the sleep study was just 4 hours [77]. A recent study showed

Table 22.2 Prospective studies that examined the association between OSA (or surrogate markers like snoring) and incident T2DM. Patients in these studies were free from T2DM at baseline

Study	Country	Population	Follow up (year)	OSA diagnosis	T2DM diagnosis	Results	Notes
Elmasry et al. [32] 2000	Sweden	2668 (all men, aged 30–69 years)	10	Questionnaire	Questionnaire	DM development: 5.4% vs. 2.4% with vs. without habitual snoring respectively ($p < 0.001$).	Adjusted for: age, weight gain, smoking, alcohol dependence, and physical inactivity
						13.5% vs. 8.6% for obese snorers vs. obese nonsnorers, respectively ($p = 0.17$).	
						OR (95% CI): 7.0 (2.9–16.9) vs. 5.1 (2.7–9.5) for obese snorers vs. obese nonsnorers	
Al-Delaimy et al. [103] 2002	USA	69852 (all female nurses, all nondiabetics at baseline)	10	Questionnaire	Self-reported and questionnaire	Snoring was associated with risk of diabetes (occasional vs. nonsnoring, RR 1.48; 95% CI 1.29–1.70; regular vs. nonsnoring, RR 2.25; 95% CI 1.91–2.66)	Adjusted for age and BMI
Reichmuth et al. [104] 2005	USA	1387	4	PSG	FPG physician diagnosis	Adjusted OR for developing DM with an AHI of 15 or more: 1.62 (95% CI 0.67–3.65)	Adjusted for age, sex, and body habitus
Marshall et al. [105] 2009	Australia	295 (population-based)	4	PSG	Physician diagnosis or FPG	Moderate to severe OSA was an independent risk factor for incident diabetes (OR = 13.45; 95% CI 1.59–114.11)	Adjusted for age, gender, waist circumference, BMI, BP, and HDL. Large 95% CI due to small number of incident diabetes
Botros et al. [106] 2009	USA	544	2.7	PSG	Physician diagnosis and FPG	Adjusted HR per quartile of OSA severity = 1.43 (95% CI 1.10–1.86)	OSA defined as AHI ≥ 8. Adjusted for age, sex, race, BMI, baseline fasting glucose, weight change
Celen et al. [107] 2010	Sweden	168 (without DM from a sleep clinic)	16	PSG	Physician diagnosis	Incident T2DM: 15.5% vs. 24.6% ($p = 0.02$). OSA was a predictor of incident T2DM in women (OR 11.8; 95% CI 1.1–121.7, $p = 0.04$) but not men after adjustment	Adjusted for age and BMI
Lindberg et al. [42] 2012	Sweden	141 (all men without DM)	11	Overnight respiratory monitor	OGTT	ODI > 5 was a predictor of developing DM (adjusted OR 4.4; 95% CI 1.1–18.1)	Adjusted for age, BMI, change in BMI, HTN, and CPAP treatment

Table 22.3 Summary of studies that examined OSA prevalence in patients with T2DM

Study	Population	Samples size	OSA diagnosis	OSA prevalence	Notes
Brooks et al. [109] 1994	Australia BMI > 35	31	Ambulatory sleep monitoring	70% moderate to severe OSA	Sample was selected from a larger population based on OSA symptoms
Elmasry et al. [51] 2001	Hypertensive men, 21% had diabetes. Age 61.4 (8.0), BMI 29.3 (4.5)	116	PSG OSA defined as AHI ≥ 20	36% in the diabetes group	The sample that had PSG was chosen based on questionnaires
Resnick et al. [110] 2003	A subgroup from the Sleep Health Heart study	470	PSG OSA defined as RDI ≥ 5. Moderate to severe RDI ≥ 15	OSA prevalence 57.8%. Moderate to severe 23.8%	Self-reported diabetes diagnosis or use of medications
West et al. [111] 2006	All male, mixed primary and secondary care populations, UK. Age 61.2 (9.7), BMI 29.6 (5.4)	1676	Oximetry OSA defined as ODI > 10	23%	Population screened by questionnaires. A subgroup was selected for oximetry
Einhorn et al. [112] 2007	Consecutive adults with T2DM from a diabetes clinic in the USA	330	Single-channel device that measured nasal airflow. OSA defined as AHI ≥ 10	48% In moderate to severe OSA: 36%	
Laaban et al. [113] 2009	Consecutive hospitalized patients with poorly controlled T2DM	303	Overnight ventilatory polygraphic study. OSA defined as RDI ≥ 5. Moderate to severe RDI ≥ 15	OSA: 63% Moderate to severe: 29%	
Foster et al. [114] 2009	Community-based population from USA (19.1% Afro-Caribbean). Age 61.3 (6.5), BMI 36.5 (5.8)	306	PSG OSA defined as AHI ≥ 5. Moderate to severe OSA: AHI ≥ 15/30	86% 30.5% for moderate OSA; 22.6% for severe OSA	Only overweight or obese individuals were included
Lam et al. [115] 2010	Randomly selected patients from a teaching hospital diabetes clinic in China. Age 57.3 (9.3), BMI 26.0 (4.6)	165	PSG OSA defined as AHI ≥ 5. Moderate to severe OSA: AHI ≥ 15	53.9% had OSA; 32.7% had moderate to severe OSA	Patients with RRT were excluded
Schober et al. [116] 2011	Secondary care sample from Germany	498	Multichannel respiratory device. OSA defined as AHI ≥ 15	37.4%	This study also included patients with type 1 diabetes; OSA prevalence 10.3%
Pillai et al. [117] 2011	Consecutive patients from secondary care diabetes obesity clinic in the UK	52	PSG	58%	Participants had risk factors for OSA
Tahrani et al. [118] 2012	Randomly selected patients from secondary care in UK, 45% are South Asians. Age 57 (12), BMI 34.4 (30.9–39.5)	234	Multichannel cardiorespiratory device. OSA defined as AHI ≥ 5	65% Moderate to severe OSA: 26%	Patients with RRT were excluded. Prevalence was not the primary outcome of the study
Heffner et al. [119] 2012	Case notes study from primary care in the US. Age 64 (14.1), BMI 33.7 (8.3)	16066	Physician diagnosis	18% of known OSA; 23% had OSA amongst obese patients	This study did not screen for OSA, it simply reports the prevalence of known OSA, hence the lower prevalence than other studies

PSG, polysomnography; RRT, Renal Replacement Therapy.

that following adjustment for age, gender, obesity, smoking status, hypertension and antihypertensives, AHI correlated with HbA1c in patients with prediabetes but not in those with T2DM or normoglycemia, whilst the lowest oxygen saturation correlated with HbA1c across all groups [124].

Despite the constant finding of an association between OSA and glycemic control in patients with T2DM, the impact of CPAP on glycemic control has not been evaluated widely and the results were not consistent (Table 22.4). Several studies [71,109,125–129] have evaluated CPAP treatment; of these, only one is a randomized clinical trial [71], with the rest being uncontrolled pre/post assessments (Table 22.4). The one controlled study showed no change in HbA1c after CPAP therapy for 3 months. The lack of positive effect could be attributed to the small study sample, the limited duration of follow-up, the suboptimal adherence to CPAP (3.6 hours per night) or a true lack of effect. In marked contrast, uncontrolled studies have shown improvements in insulin sensitivity [109,125], postprandial hyperglycemia [126], glycemic variability [129], or HbA1c [126,127] (Table 22.4). A recent meta-analysis found that CPAP treatment did not result in significant reductions in HbA1c (0.08 %; 95 % CI -0.26–0.42) in patients with T2DM [130]. However, new data showing that AHI only correlated with REM AHI and not non-REM AHI suggest that longer usage of CPAP beyond 4 hours is needed as most REM sleep occurs in the latter half of the night [131]. Indeed recent preliminary results showed that 1 week of in-laboratory (8 hours of sleep) CPAP treatment resulted in a decrease of 11.2 and 19.8 mg dL^{-1} in the average 24-hour and post-breakfast glucose levels, respectively, with a 45% decrease in the dawn phenomenon as well [132]. However, enforcing 7–8 hours per night of CPAP usage in real life is a huge challenge. In addition, it is important to note that the diabetes duration of patients in this study was relatively short (3.2 years) unlike in previous studies; this is important as IR and β-cell dysfunction may be more reversible in such a population.

OSA and diabetes-related complications

Recently, there has been increasing interest in the association between OSA and diabetes-related complications. There is one cross-sectional published study regarding the association between OSA and macrovascular complications in T2DM, but several studies have examined the association between microvascular complications and OSA in T2DM. Most of these studies are cross-sectional in nature but more recently prospective studies proving causality have been published. Many of these studies fail to adjust for many of the possible confounders.

The hypothesis that OSA can cause micro- (as well as macro-) vascular complications in T2DM is based on the observation that OSA and intermittent hypoxia result in similar molecular consequences in patients without T2DM to those caused by hyperglycemia and result in diabetes-related complications; including increased oxidative stress and advanced glycation end-products, production and activation of the protein

kinase C pathway and its molecular perturbations resulting in micro- and macrovascular disease and endothelial dysfunction (Figure 22.3) [118]. Recent work has shown that OSA in patients with T2DM is associated with increased oxidative stress and nitrosative stress and impaired microvascular and endothelial function despite adjustment for a wide range of confounders [118]. OSA has also been shown to be associated with poly (ADP ribose) polymerase (PARP) activation in patients with T2DM (Tahrani, unpublished data).

One cross-sectional analysis from the Look AHEAD study showed that AHI is associated with stroke (adjusted OR 2.57; 95% CI 1.03–6.42), but there was no association with coronary artery disease [133]. Cardiovascular disease (CVD) in this study was self-reported.

Three studies have examined the association between OSA and diabetic retinopathy (DR). In the first study, Shiba et al. used a highly selected population of 219 Japanese patients who were undergoing vitreous surgery and used pulse oximetry to diagnose OSA [134]. Patients with proliferative DR had higher ODI compared to those with nonproliferative DR. After adjustment for age, HbA1c, and hypertension, higher oxygen saturations were found to be protective against proliferative DR [134]. The same investigation has also shown that OSA is associated with angle neovascularization in proliferative DR [135]. Another study included 118 men from primary and secondary care in the UK [136] and found that OSA was independently associated with DR and maculopathy after adjusting for age, BMI, diabetes duration, and hypertension [136]. Another cross-sectional study from the UK that included 226 patients recruited from a secondary care diabetes clinic and used multichannel respiratory devices to diagnose OSA, found that patients with OSA are 3–4 times more likely to have sight-threatening retinopathy, preproliferative/proliferative retinopathy or maculopathy after adjustment for a wide range of confounders, such as age, obesity, diabetes duration, glycemic control and medications amongst others [137]. Furthermore, a longitudinal follow-up of the last mentioned cross-sectional study showed that patients with OSA are more likely to develop preproliferative or proliferative DR despite adjustment for confounders (OR 6.6; 95% CI 1.2–35.1, $p = 0.03$) [137]. In an uncontrolled, hypothesis-generating study of 28 patients with clinically significant macular edema, 6 months of treatment with CPAP was associated with improvement in visual acuity without an impact on macular edema [138].

The association between OSA and diabetic peripheral neuropathy (DPN) has been examined in one cross-sectional study that included South Asians and white Caucasians with T2DM recruited from the diabetes clinic of a secondary care hospital in the UK. This study used portable multichannel respiratory devices to diagnose OSA, the Michigan Neuropathy Screening Instrument to diagnose DPN, and the 10 g monofilament perception to diagnose foot insensitivity. Patients with OSA were three times (OR 2.82; 95% CI 1.44–5.52) and four times (OR 3.97; 95% CI 1.80–8.74) more likely to have DPN and

Table 22.4 Summary of studies that examined the impact of CPAP treatment on glycemic control in patients with T2DM

Study	Population	Study design	Control group	Matching or confounder adjustment	Outcome measure	Duration	CPAP usage	Effectiveness
Brooks et al. [109] 1994	n = 10 Australia Obese T2DM (BMI > 35)	Pre and post	No	No	Glucose disposal during hyperinsulinemic euglycemic clamp	4 months	NR	+
Harsch et al. [125] 2004	n = 9 Severe OSA BMI 37.3 (5.6) HbA1c 6.4 (0.7)%	Pre and post	No	No	ISI established by euglycemic hyperinsulinemic clamp	3 months	5.8 h/n	–
Babu et al. [126] 2005	n = 25 Severe OSA BMI 42.7 (8.7) HbA1c 8.3 (2.2) Diabetes duration 8.6 (6.3)	Pre and post	No	No	72 h CGMS and HbA1c	3 months	4.2 h/n	+
Hassaballa et al. [127] 2005	n = 38 Severe OSA BMI 42 (9.5) HbA1c 7.8 (1.4)%	Pre and post	No	No	HbA1c	4 months	4 h/n	+
West et al. [71] 2007	n = 42 Age 57.8 (10.4) BMI 36.6 (4.9) HbA1c 8.5 (1.8)	RCT	Yes	N/A	HbA1c	3 months	3.6 h/n	–

Source: Adapted from Tahrani et al. [118].

foot insensitivity, respectively, compared to those without OSA [118]. OSA patients were also more likely to have reduced vibration perception and absent ankle jerk reflex [118]. OSA and nocturnal hypoxemia severity were associated with DPN and its severity [118]. Unpublished data from the same study showed that OSA was also associated with lower intra-epidermal nerve fiber density in skin biopsies (Tahrani, unpublished data) suggesting that OSA may cause large as well as small nerve fiber dysfunction.

The association between OSA and diabetic nephropathy has been examined in two studies. In one study of 237 patients, snoring (as a surrogate marker of OSA) was found to be independently associated with microalbuminuria [139]. Another study showed that OSA was associated with diabetic nephropathy (defined as microalbuminuria, microalbuminuria and/or reduced eGFR) in patients with T2DM after adjustment for a wide range of confounders; patients with end-stage renal disease were excluded from this study [140]. A 2.5 year follow-up of the latest study showed that the decline in eGFR was greater in patients with T2DM and OSA compared to those with OSA alone (−6.8% [−16.1–2.2%] vs. −1.6% [−7.7–5.3%], $p = 0.002$) and that OSA was a predictor of study-end eGFR despite adjustment for confounders [140].

OSA is also associated with autonomic neuropathy and increased sympathetic activity [141]. It is likely that both recurrent hypoxia [95] and recurrent arousals [96] contribute to the activation of the sympathetic system. Obese subjects with autonomic neuropathy develop more frequent and more prolonged hypopnea/apnea in comparison to obese subjects without autonomic dysfunction whether or not they had T2DM [142].

Other OSA comorbidities

Road traffic accidents

Several cross-sectional studies using driving simulators showed worse driving performance and increased risk of road traffic accidents in patients with OSA [143]. In a sample of 913 employed adults whose motor vehicle accident history was obtained from a state-wide database covering the period 1988–1993, men with OSA (AHI ≥ 5) were more likely to have at least one accident in 5 years compared to those without OSA (age and miles driven adjusted OR 4.2 for AHI 5–15, and 3.4 for AHI > 15) [10,144]. Men and women combined with AHI > 15 (vs. no OSA) were significantly more likely to have multiple accidents in 5 years (OR 7.3) [10,144]. Similar results were found in another case-control study from Spain [145]. Interestingly, neither of these two studies showed a relationship between reported sleepiness and the road traffic accidents nor was there a dose relation between OSA severity and the likelihood of involvement in an accident.

Cardiovascular mortality and morbidity

OSA has been associated with sustained hypertension and lack of the normal nocturnal dipping of blood pressure (BP). Nondipping of BP in OSA patients was examined prospectively in a subsample of 328 adults enrolled in the Wisconsin Sleep Cohort Study who completed 2 or more 24-hour ambulatory BP studies over an average of 7.2 years [146]. After adjustment for many confounders, the adjusted OR (95% CI) of incident systolic nondipping for baseline AHI 5–14.9 and ≥15, vs. AHI < 5, were 3.1 (1.3–7.7) and 4.4 (1.2–16.3), respectively [146]. In a cross-sectional analysis of 6132 middle-aged and older persons

(aged $\geq$ 40 years) from the Sleep Heart Health Study, the OR (95%CI) for hypertension for the highest vs. the lowest category of AHI was 1.37 (1.03–1.83, $p = 0.005$) after adjustment for BMI, neck circumference, waist-to-hip ratio (WHR), alcohol, and smoking [147]. The associations of hypertension with OSA were seen in men and women, older and younger, all ethnic groups, and among normal-weight and overweight individuals [147]. In another prospective study based on the Wisconsin Sleep Cohort Study, the relation between OSA and hypertension in 709 participants over 4 years was examined [148]. After adjustment, and relative to an AHI of 0 at baseline, the OR for the presence of hypertension at follow-up were 1.42 (95% CI: 1.13–1.78), 2.03 (1.29–3.17) and 2.89 (1.46–5.64) for an AHI of 0.1–4.9, 5.0–14.9, and $\geq$15.0, respectively ($p = 0.002$ for the trend) [148].

Several cross-sectional and case-control studies showed an association between OSA and cardiovascular disease (CVD) [10]. Three prospective studies used more accurate methods to diagnose OSA (i.e., polysomnography) [149–151]. In a study of a 182 consecutive middle-aged men free of CVD at baseline who were followed for 7 years, the incidence of CVD was 36.7% of patients with OSA vs. 6.6% of subjects without OSA ($p < 0.001$) [149]. OSA was an independent predictor of CVD (OR 4.9; 95% CI 1.8–13.6) after adjustment for confounders [149]. CPAP treatment was associated with lower incidence of CVD compared to those untreated (56.8% vs. 6.7%, $p < 0.001$) [149]. In another prospective study in which men with OSA were followed for a mean of 10.1 years, patients with untreated severe OSA had a higher incidence of fatal CVD and nonfatal CVD than did untreated patients with mild-moderate OSA, simple snorers, patients treated with CPAP, and healthy participants [150]. After adjustment for confounders, untreated severe OSA significantly increased the risk of fatal (OR 2.87; 95% CI 1.17–7.51) and nonfatal (3.17; 1.12–7.51) CVD compared with healthy participants [150]. In another important prospective study, 1022 patients were followed up for a median of 3.4 years [151]. After adjustment for confounders, OSA was significantly associated with stroke or death (hazard ratio (HR), 1.97; 95% CI 1.12–3.48; $p = 0.01$) [151]. Furthermore, in patients with stable coronary artery disease, patients with OSA had larger atherosclerotic plaque volume as assessed by intravascular ultrasound and AHI correlated positively with the plaque volume measured by US ($r = 0.6$, $p = 0.01$) [152] or CT angiogram ($r = 0.4$, $p = 0.02$) [153]. The role of nocturnal events in OSA in the development of myocardial infarction is further supported by a study that showed patients with OSA were more likely to develop acute myocardial infarction between 12 AM and 6 AM compared to patients matched for comorbidities but who did not have OSA (32% vs. 7%, $p = 0.01$) [154].

The impact of OSA on mortality was examined in the Wisconsin Sleep Cohort Study [155] and the Sleep Heart Health Study [156]. In 18-year follow-up, there was a step-wise reduction in survival with worsening OSA. The adjusted hazard ratio (HR; 95% CI) for all-cause mortality with severe vs. no OSA was 2.7 (1.3–5.7) after adjustment for possible confounders [155]. In 6441 men and women who were followed up for 8.2 years; compared to those without OSA (AHI < 5 events per hour), the HR for all-cause mortality in those with mild, moderate, and severe OSA were 0.93 (95% CI 0.80–1.08), 1.17 (95% CI 0.97–1.42), and 1.46 (95% CI 1.14–1.86), respectively, after adjustment for age, sex, race, smoking status, BMI, and prevalent medical conditions [156]. Measures of intermittent hypoxemia, but not sleep fragmentation, were independently associated with all-cause mortality [156].

OSA management

OSA should be treated promptly and the aim of treatment is to reduce the morbidity and mortality associated with this condition. Weight loss and positional treatment (i.e., avoiding the position in which most episodes occur, which is usually the supine position) are important aspects of treatment. As with all obesity-related disorders, weight loss (regardless of the means) can result in significant improvements in OSA. In a randomized controlled trial of intensive lifestyle intervention in 264 patients with OSA and T2DM (the Sleep AHEAD study), weight loss of 11 kg on average in the treatment group resulted in a reduction in the AHI of about 10 events per hour [157]. Similar results were found in a study of men with OSA, in which 10% weight loss resulted in improvements in the RDI by about 16 events per hour [158]. Weight loss after bariatric surgery has also been associated with significant improvements in OSA severity [159].

Mandibular advancement devices (MAD) are effective in treating patients with mild to moderate OSA. They work by pulling the tongue forward or by moving the mandible and soft palate anteriorly, enlarging the posterior airspace, which results in opening and increasing the airway size. MAD are considered as a second-line treatment for patients with mild to moderate OSA who cannot tolerate CPAP [160].

Surgery has a limited role in patients with OSA and produces variable results [160]. If the patient has upper airway obstruction (such as tonsils or tumors) then surgery is the most important aspect of the treatment, otherwise its role is limited and it is usually associated with significant side effects [160].

CPAP is the mainstay of treatment for patients with OSA. CPAP works by providing a "pneumatic splint" by delivering an intraluminal pressure that is positive with reference to the atmospheric pressure and by increasing lung volumes [161]. CPAP treatment has been shown to reduce AHI, reduce BP, improve sleepiness, improve quality of life, improve cognitive function, and reduce motor vehicle accidents [161]. Furthermore, evidence from an observational study suggests that CPAP treatment reduces the risk of cardiovascular events [150]. An in-depth review on CPAP, its technical aspects, evidence behind its use, and its complications can be found elsewhere in [161].

Impact of T2DM on OSA

Although the bulk of this chapter describes the impact of OSA on glucose metabolism and T2DM, this association could be directional and having IR or T2DM may have an impact on pre-existing OSA and result in the development of "new" OSA or CSA.

In a study of 3565 participants, who were followed up for a 6-year period, the presence of a history of witnessed apneas was an independent predictor of incident sleep apnea [162]. After adjustment for age, sex, and waist circumference, the standardized OR for incident sleep apnea for HOMA-IR was 1.31 (1.13–1.51). This suggests that not only can sleep apnea result in dysglycemia as shown by longitudinal studies, but that pre-existing dysglycemia also predicts the development of sleep apnea. This may be related in part to the loss of upper airway innervations or the autonomic dysfunction that can occur in patients with dysglycemia; autonomic neuropathy has been implicated in the central respiratory centre response to hypercapnic stimulus [163] and may result in changes in respiratory control resulting in CSA as seen in other conditions such as multisystem atrophy (Shy–Drager syndrome) [164].

CSA has indeed been shown to be common in patients with T2DM. In a subgroup analysis of the Sleep Heart Health Study, there were significant differences in RDI, sleep stages, central apnea index, and periodic breathing between patients with and without DM. However, most of these differences lost their statistical significance after adjusting for confounders with the exception of percent time in REM sleep and prevalence of periodic breathing [110]. Similarly, Sanders and colleagues found a greater prevalence of CSA in patients with DM compared to those without (3.8% vs. 1.8%, DM vs. non-DM patients, respectively, $p = 0.002$) [165].

The natural history of OSA in patients with T2DM and the impact of T2DM on pre-existing OSA is currently unknown, but the ongoing Sleep AHEAD study will be able to answer this question.

Summary and future directions

OSA is a very common medical disorder that is associated with significant morbidity and mortality. OSA is associated with obesity, hypertension, insulin resistance, and possibly impaired β-cell function. OSA is associated with several mechanisms that lead to insulin resistance and β-cell dysfunction including intermittent hypoxia, inflammation, sympathetic activation, activation of the hypothalamic pituitary adrenal axis, reduction in adiponectin, increased leptin, and the development of nonalcoholic steatohepatitis. As a result, dysglycemia is very common in patients with OSA.

OSA is associated with worse glycemic control in patients with T2DM but CPAP treatment does not seem to improve glycemic control. The impact of CPAP treatment on other metabolic parameters in patients with T2DM including blood pressure and dyslipidemia are also needed. OSA is associated with increased oxidative and nitrosative stress and impaired microvascular and endothelial function in patients with diabetes, hence it is not surprising that OSA is associated with diabetes-related microvascular complications. However, prospective and interventional studies are required to confirm causality. In addition, T2DM is associated with CSA, and not only OSA, and this seems to be related to autonomic dysfunction.

The field of OSA in patients with T2DM is still in its infancy and most of the work in regard to OSA in patients with T2DM has focused on glycemic control, it is time to address the impact of OSA on other aspects of T2DM.

Declaration

SECTION V

PATHOGENESIS

CHAPTER 23

The insulin resistance syndrome

Naveed Sattar, Paul Welsh and David Preiss

Institute of Cardiovascular and Medical Sciences, BHF Glasgow Cardiovascular Research Centre, University of Glasgow, Glasgow, UK

Key points

- Aside from insulin's role to regulate glucose metabolism via effects on skeletal muscle, liver, and adipose tissue, it has effects on numerous other tissues (e.g. endothelium and immune system) and risk pathways and, consequently, insulin resistance is linked to many risk factor perturbations.

- The simplest clinically recognizable and most dominant feature of insulin resistance is presence of obesity, whether measured by body mass index (BMI) or elevated waist circumference.

- The characteristic insulin resistance lipid pattern is one of elevated triglyceride and lower HDL-cholesterol concentrations and these features, together with obesity and elevated blood pressure, have formed the cornerstone of most versions of metabolic syndrome diagnostic criteria.

- More recently, elevated liver fat, recognizable in some by elevated ALT and GGT levels, has emerged as a key and clinically important feature of insulin resistance in many individuals.

- Insulin resistance is also linked variably to alterations in adipokines, vascular dysfunction and immune regulation, and although the clinical relevance of these associations remain to be fully elucidated, novel anti-inflammatory agents are being trialed to lower glucose levels in diabetes.

- An attempt to bring the insulin resistance syndrome to wide clinical utility was made by introducing simpler metabolic syndrome criteria into the ATP III guidelines.

- Whilst the afore-mentioned metabolic syndrome was demonstrated to be clearly associated with cardiovascular events, prospective research eventually showed it did not improve cardiovascular risk prediction.

- Nevertheless the insulin resistance or metabolic syndrome is, arguably, conceptually useful and it may have led more clinicians to consider (and target) glycemia and adiposity parameters in their patients.

- Future research in this area should be better directed at determining causes and consequences of insulin resistance by harnessing the power of genetics; so-called Mendelian randomization studies.

- Finally, the strongest risk factor for insulin resistance remains excess adiposity and, as such, preventing or targeting excess weight gain must remain the major goal in public health to reduce the incidence of its clinical sequelae, in particular, type 2 diabetes.

What is insulin resistance?

Broadly, insulin resistance can be defined as an abnormal biologic response to insulin; insulin, whether endogenous or exogenous in origin, has limited ability to reverse a hyperglycemic metabolic state. Thus a person with insulin resistance is, almost inevitably, progressing towards developing frank type 2 diabetes (T2DM) if an intervention (usually lifestyle) is not implemented. Due to the very close link between diabetes and insulin resistance, no formal clinical definition of insulin resistance has emerged. We will discuss the potential clinical use of the *insulin resistance syndrome* and the *metabolic syndrome* later in the chapter. For now, we focus on investigation of insulin resistance as a useful entity for research concepts, and in particular discuss its biologic consequences by describing its associated risk factor perturbations.

Multiple roles of insulin

To understand the link between many novel parameters and insulin resistance, and thereby their association with T2DM, it is important to appreciate that insulin imparts its effects not only on skeletal muscle but also on many tissues including adipose, liver, endothelium, and immune cells. Thus, insulin is relevant not simply for glucose uptake and metabolism, but also for (i) suppression of free fatty acid (FFA) release from adipose tissue, (ii) limiting hepatic triglyceride synthesis, (iii) helping to maintain endothelial homeostasis, (iv) regulating thrombotic cascades, and (v) potentially playing a role in regulating inflammatory cascades (Figure 23.1). With increasing adiposity, fat cells become enlarged and less responsive to insulin, that is, they become insulin resistant. The subsequent excessive release of FFAs into the portal circulation in part drives excess hepatic fat accumulation and triglyceride synthesis (leading to elevated circulating triglyceride levels and associated changes in circulating lipids) and muscle fat accumulation. Excess fat in the latter two organs is considered to enhance their insulin resistance;
Figure 23.1 Multiple roles of insulin. The figure illustrates the relevance of insulin action not simply to skeletal muscle glucose uptake, but also adipose, liver, endothelium, and immune cell function. As fat cells enlarge with greater obesity and become more insulin resistant, they enhance (e.g. IL-6) or suppress (e.g. adiponectin) release of many agents into the circulation. Similarly, a subclinical "fatty liver," dysfunctional endothelium, and irritated immune cells in insulin resistance release an array of molecules into the circulation. As a result, the circulating concentrations of such parameters give indications as to the degree of insulin resistance and also therefore associate with future risk for type 2 diabetes.

specifically, excess fat in the liver limits glucose storage (in the form of glycogen) but enhances glucose synthesis via gluconeogenesis, whereas excess fat in muscle lessens glucose uptake. The combined effects thus promote hyperglycemia. This hyperglycemia can be offset for many years by an increase in pancreatic insulin secretion, and hence hyperinsulinemia accompanies insulin resistance. In persons who develop T2DM, the pancreas has eventually become "exhausted"—it can no longer produce sufficient insulin to counteract the hyperglycemic drive—and glucose concentrations rise into the diabetic range.

How do we measure insulin resistance?

The gold standard method for measuring insulin resistance focuses on maintaining a normal blood glucose level in a hyperinsulinemic state—the so-called euglycemic hyperinsulinemic clamp. This technique involves infusing insulin at supraphysiologic rates based on body size, while also infusing glucose at the necessary rate to maintain euglycemia. The use of stable isotopes provides further information on the relevant roles of the liver and peripheral tissue (muscle and adipose tissue). When a steady state is achieved, the glucose infusion rate is essentially a measure of the ability of all tissues to respond to insulin and take up glucose for a standard insulin dose [1]. Thus, the global sensitivity to insulin is comparable between patients or participants. There are several different specific

methodological variations of this approach to measure insulin resistance, each with strengths and weaknesses, although the aim is always similar. The major drawback of this gold-standard approach is its labor-intensive and time-consuming nature. Thus, it is not a practical test for routine screening or for large epidemiologic studies. Other dynamic tests to measure sensitivity to insulin are available but are infrequently used in clinical settings (Table 23.1).

Simple characteristics associated with insulin resistance

If one looks at any reputable risk score for the prediction of T2DM, certain parameters always appear—age, gender, adiposity measures, family history of T2DM, and ethnicity. Of all of these, rising obesity levels are strongly associated with insulin resistance whatever the other characteristics of an individual and, as such, fat accumulation is the primary risk factor that drives increasing insulin resistance at a population level. That noted, the other risk factors are also of importance in considering an individual's risk. For example, an older Asian male with a family history of T2DM will have greater insulin resistance for a given weight than younger white females without a family history of diabetes. In other words, nonmodifiable characteristics (age, sex, ethnicity, family history) interact with adiposity to determine degree of insulin resistance and

Table 23.1 Common methods of measurement of insulin resistance

Method name	Method summary	Advantages	Disadvantages
Direct model techniques			
Euglycemic hyperinsulinemic clamp (EUC)	Steady i.v. insulin infusion in one arm, glucose infusion in the other to achieve "clamped" euglycemic state.	The gold-standard method. Radio-labeled glucose tracer can be used to investigate tissue-specific glucose disposal. Hyperinsulinemic-hyperglycemic clamp modification estimates β-cell function.	Labor intensive, time-consuming, and requires experienced operators. Test will run from early morning to early afternoon. Multiple tests to determine euglycemia achieved. Ideal insulin infusion rate varies according to study cohort. Hypoglycemia may occur.
Insulin sensitivity test (IST)	Infusion of defined glucose load and steady-state insulin to a single arm over ~3 h. Somatostatin can also be infused to limit the effect of endogenous insulin. Glucose concentration from contralateral arm every 10 min in last 30 min determines SI.	Highly reproducible. Easier to achieve steady state and shorter method than EUC. Fewer blood tests.	Still impractical for clinical setting/large studies. Hypoglycemia possible in insulin-sensitive individuals.
Insulin tolerance test (ITT)	Simplified version of IST. Measures fall in glucose for 15 min after i.v. bolus of insulin.	Short test. Little opportunity for interference from endogenous factors.	Only measures skeletal muscle IR. Increased risk of hypoglycemia.
Indirect "minimal" models			
Frequently sampled IV glucose tolerance tests (FSIVGGT)	Several variations of this model exist. Glucose is infused (with or without insulin) and glucose is measured on multiple occasions over 3 h. SI is calculated from a curve fit observing glucose disappearance.	Slightly easier than EUC. SI often correlates very well with EUC.	Many assumptions made about dynamics of glucose disposal (no steady state).
Continuous infusion of glucose with model assessment (CIGMA)	Like ITT, a bolus infusion of glucose is administered. Blood samples for glucose and insulin measures are drawn at a few time points after around 1 h. A mathematical model derives SI.	Not as time-consuming as FSIVGGT.	Not well validated.
Oral glucose tolerance test (OGTT)	This is a routine test for the clinical diagnosis of diabetes when simpler blood tests are ambiguous. Often involves a 75 g or 100 g dose of glucose, and measuring glucose and insulin at frequent intervals.	A more physiologic test of glucose disposal than i.v. loads.	Measures glucose tolerance and not aligned to insulin sensitivity per se.
Fasting methods			
Fasting insulin	β-cell insulin secretion is steady and will be lower in those with better SI in the fasting state.	Quick and inexpensive single assay. Easy to develop reference ranges and interpret.	Assumption of fasting and steady-state metabolism. Cannot be used in diabetic patients as a measure of IR due to insulin-based treatment.
Glucose:insulin ratio	Used by some researchers in women with PCOS. Essentially corresponds to 1/insulin in the normal fasting glucose range.	Quick and inexpensive.	Cannot be used in diabetic patients; would paradoxically have a higher G:I ratio, indicating better SI.

(continued overleaf)

Table 23.1 (*continued*)

Method name	Method summary	Advantages	Disadvantages
HOMA-IR	Homeostasis model assessment (HOMA) is mathematical model of glucose and insulin interactions. HOMA-IR = insulin (U mL^{-1}) * glucose (mmol L^{-1})/22.5. The denominator of 22.5 is a normalizing factor; i.e., a normal insulin*glucose. Therefore a normal HOMA-IR = 1. A "HOMA2" model has also been developed.	Useful for SI evaluation in individuals with glucose intolerance, mild to moderate diabetes, etc. Can be used in large studies.	Not suitable in those with impaired or β-cell function. Poorly validated in animal models.
Quantitative insulin sensitivity check index (QUICKI)	Since fasting insulin levels are skewed, log-normalized data can be used in models. QUICKI = 1/Log (insulin U mL^{-1}) + Log (glucose, mg dL^{-1}).	Better correlation with SI by EUC than HOMA-IR. Among the best validated measures in humans.	Log-normalized data unattractive for clinical use.

IR, insulin resistance; PCOS, polycystic ovarian syndrome; SI, sensitivity to insulin.

T2DM risk. Interestingly, as recently reviewed [2], these simple characteristics give good prediction of T2DM risk (area under receiver operator curve around 80%) and thus the benchmark for biomarkers to meaningfully improve prediction beyond simple measures is high.

Concept of ectopic fat as a cause of tissue insulin resistance

It appears that individuals prone to T2DM (based in part on their nonmodifiable characteristics) show a greater propensity to accumulate visceral or ectopic fat for a given weight. Interestingly this characteristic, in turn, may be a downstream consequence of "impaired" subcutaneous fat storage capacity, the mechanisms of which deserve further research. As an extreme example of this concept, lipodystrophic individuals have an impaired ability to store subcutaneous fat and, as a consequence, they accumulate fat in visceral and ectopic tissues and so have marked insulin resistance [3]. It is also apparent that certain ethnic groups at heightened diabetes risk may have a tendency to store fat centrally sooner (i.e., at lower average BMI) than European whites and consequently develop diabetes at lower average BMI values and around a decade earlier [4]. At the other extreme, there are many individuals, particularly women, who despite attaining very high BMIs, even as high as 50 to 60 kg m^{-2}, remain insulin sensitive and normolipemic. Imaging studies have shown these individuals to have low levels of visceral and ectopic fat but a high subcutaneous fat content [5]. In other words, the location of fat storage (subcutaneous vs. visceral/ectopic) appears critical as to the BMI and time that an individual develops metabolic complications linked to insulin resistance. Figure 23.2 summarizes the concept of ectopic fat and its importance to insulin resistance.

Pathways linked to insulin resistance

From the preceding observations on the actions of insulin and the role of ectopic fat in exacerbating insulin resistance, a number of linked metabolic perturbances can be predicted. The most clinically relevant and interesting pathways are discussed later with an attempt to draw out potential causal associations where relevant.

Lipid alterations in insulin resistance syndrome

Given insulin's role in suppressing FFA release, it is clear that insulin resistance must be associated with raised triglyceride levels. Similarly, given that in most individuals triglyceride levels inversely correlate with HDL-cholesterol levels, low HDL-cholesterol is a commonly recognized feature in insulin resistance. Beyond these two changes, it has been clearly shown that higher apolipoprotein B levels and greater preponderance of small dense LDL are linked to insulin resistance [6]. Whilst this lipid pattern is often considered to be linked to increased vascular risk in the prediabetes individual, the causal nature of these associations remains debated. Furthermore, it is now clear that elevated triglyceride levels in most individuals more strongly indicate diabetes than vascular risk [7]. There is also now strong evidence that once cholesterol and HDL-cholesterol are included in cardiovascular risk scores, addition of triglyceride or other lipid fractions adds minimally to prediction of cardiovascular events [8,9]. Despite this, evidence from a large genetic study is potentially consistent with a causal role for triglycerides in heart disease [10]. Thus it is possible for a risk factor to be causal, but offer redundant information in terms of risk scores.

Liver markers and insulin resistance

In terms of chronology, gain of liver fat appears to immediately precede development of diabetes in most individuals whereas
Figure 23.2 Simple concept of ectopic fat and development of insulin resistance and frank type 2 diabetes. This figure provides a simple conceptual illustration of the development and location of ectopic fat (and thus worsening insulin resistance) in individuals once they have "overwhelmed" their ability to store safe subcutaneous fat. Certain factors such as gender (females having greater storage capacity), genetics (with family history of diabetes as a broad proxy measure), ethnicity (e.g. South Asians) and aging have relevance to an individual's ability to store fat subcutaneously. In temporal terms, it may be liver fat accumulation is closer to the time of development of diabetes whereas muscle insulin resistance is an earlier development. Perivascular fat may contribute to vascular dysfunction via a process of adverse vasocrine signaling leading in turn to impaired nutrient blood flow—that is, vascular insulin resistance. Finally, some recent evidence indicates excess fat may also accumulate in the pancreas to contribute to β-cell dysfunction, and thus development of diabetes. IR, insulin resistance.

muscle insulin resistance appears to be a longer standing and earlier abnormality [11]. Considerable recent work has focused on the role of the liver in the development of diabetes and, linked to this, the condition of nonalcoholic fatty liver disease (NAFLD) has been shown to be very common (>50%) in T2DM and is linked to hepatic insulin resistance [12]. Several factors released by the liver have been associated with insulin resistance as shown in Table 23.2. These include ALT, GGT, SHBG, IGF-1, Ferritin, and CRP [13–17]. In terms of clinical utility, clinicians now commonly recognize the value of ALT and GGT to help define risk of NAFLD. However, whilst ALT and GGT have been shown to be linked to incident diabetes, they are not, and are unlikely to be, included in diabetes risk scores. SHBG is measured in many centers together with testosterone to derive a free androgen index ([testosterone / SHBG]*100), a parameter used in the diagnosis of polycystic ovarian syndrome (PCOS), a condition linked to insulin resistance and obesity [18]. In terms of causality, preliminary evidence suggests SHBG may be causally linked to diabetes [19] but, interestingly, not to insulin resistance. Further basic and clinical work in this area would be useful to tease apart the causal pathway.

Fetuin-A (also called alpha-2-HS-glycoprotein) is a liver-derived glycoprotein involved in calcium and phosphate transport. Recent evidence indicates that Fetuin-A may be implicated in insulin sensitivity through inflammatory signaling pathways [20]. Consequently clinical and epidemiologic studies of circulating levels of this biomarker, and its implications for disease, are now emerging.

Adipose-derived markers and insulin resistance

Whilst rising BMI or waist circumference are clearly linked to insulin resistance and risk for T2DM, a number of adipose-derived factors have attracted interest with respect to determining insulin resistance. Adiponectin, as recently reviewed [21], has been the most notable of these biomarkers. Adiponectin is unlike the other adipocyte hormones in that its concentrations decline with rising obesity. Therefore low levels predict higher risk for T2DM but there are a number of complexities in this relationship. First, it remains unclear if adiponectin measurement aids diabetes risk prediction. For instance, in the British Regional Heart Study men with adiponectin concentrations in the top third of the distribution had a 60% (95% CI 30–77%) lower risk of incident T2DM

Table 23.2 Relationship and potential causal role of factors emerging from different pathways with insulin resistance

Novel predictor	Background	Examples of association with IR in a variety of clinical studies*	Evidence of causality	Other relevant points
Liver-derived factors				
ALT/GGT	Liver transaminases are elevated in hepatic fat accumulation, NAFLD. *When* AST rise starts to parallel ALT rise, NASH is indicated.	Association with SI during EUC: $\beta = -0.18$ in men and -0.15 in women (for ALT), and $\beta = -0.17$ in men and -0.11 in women (for GGT) after adjustment for age and center [13].	Markers of ectopic fat rather than causal, though liver fat may be causally associated with insulin resistance.	ALT and GGT strongly positively associated with diabetes risk [64].
SHBG	Testosterone and estrogen circulate bound to liver-derived SHBG.	Association with SI during EUC $r = 0.15$ after adjusting for age, sex, and body fat. Null association after further adjusting for hepatic fat [14].	Evidence from MR studies that SHBG may be causal in diabetes, but no association with IR [19].	Monosaccharide-induced lipogenesis reduces hepatic SHBG expression [65].
Ferritin	Iron transporter. Circulating levels also increase during acute phase response.	Association with HOMA-IR $r = 0.20$ in Korean men and $r = 0.15$ in Korean women. Only associated with HOMA-IR in men after multiple adjustments [15].	No evidence for causality.	Unlikely to be used for diabetes prediction.
IGF-1	Insulin-like growth factor-1.	Associated with HOMA-IR after adjusting for age and sex ($r = -0.28$) [16].	Evidence in mice that IGF-1 regulates insulin and growth hormone balance in SI [66].	Several analogues available, but none examined for glycemic control.
CRP	Classical marker of the acute phase response.	Associated with SI (from IV GGT) after adjusting for age, sex, center, ethnicity, and smoking: $r = -0.37$ [61]. Strong positive association with HOMA-IR by quartiles in Framingham Offspring study [17] and other studies [67].	Clear evidence against causality [68], though upstream IL-6 may be more relevant.	Predictive clinical utility of CRP for CVD now also in doubt.
Fetuin-A	Fetuin-A is a mineral carrier. Deficiency is associated with soft tissue calcification.	Weak but significant association with HOMA-IR in a community study of Chinese participants ($\beta = 0.03$) after multiple adjustments [72].	Fetuin-A may interact with toll-like receptor 4 in altering insulin sensitivity in mouse models [20].	Increased Fetuin-A is associated with slightly reduced CVD risk among those without diabetes [69].
Adipose-derived factors				
Adiponectin	Adipose-derived hormone inversely associated with BMI. Putative insulin sensitizer.	Univariable association with SI during EUC $r = 0.28$ in women and $r = 0.42$ in men without DM [64]. After adjusting for age, sex, and measures of adiposity, this association was $r = 0.23$ [70,71].	Strong evidence of causality in animal models. Recent evidence goes against adiponectin as causally [72] related to IR or type2 diabetes in man [24].	High adiponectin associated with lower diabetes but in older individuals or those with CVD, also associated with greater total and CVD mortality.
Leptin	Adipose-derived hormone involved in appetite regulation. +ve association with BMI.	Univariable association with SI (glucose uptake) during EUC $r = -0.59$ in women and $r = -0.83$ in men without DM [73].	Absolute leptin deficiency causes IR. High levels of leptin in obesity possibly a result of "leptin resistance" causing lack of satiety.	Leptin not clinically useful to enhance diabetes prediction over simpler measures of obesity.

IL-6	Inflammatory marker—causes hepatic acute phase response. Potential causal role in CVD.	Association with SI during EUC $r=-0.23$ in a study of African Americans [71]; robust to adjustment for fat mass.	Limited evidence an IL-6 blocker increases insulin sensitivity in RA patients [74], plus indirect genetic evidence for potential causal link between IL-6R and diabetes [26].	Although potentially causal, robust intervention studies currently lacking.
PAI-1	Principal inhibitor of t-PA, thus an inhibitor of fibrinolysis.	Association with SI during EUC $r=-0.21$ in a study of African Americans [71]; robust to adjustment for fat mass. Strong positive association with HOMA-IR by quartiles in Framingham Offspring [17].	PAI-1 deficient mice do not develop obesity or IR on high-fat diet [75,76]. Lack of data in humans.	Tiplaxtinin is a small molecule inhibitor (not suitable for long-term treatment). ACE inhibitors and insulin sensitizers also reduce PAI-1.

Endothelial-derived factors

t-PA antigen	Tissue plasminogen activator is involved in fibrinolysis.	Moderate positive association with HOMA-IR in older men ($r=0.25$ after adjusting for WC). Similar results in both genders [77].	Elevated levels are a result of endothelial dysfunction; a marker of disease rather than a cause, commensurate with fibrinolytic role.	t-PA can also be released from liver and thus, hard to fully distinguish whether its links to IR represent hepatic or vascular origins.
Adhesion molecules	P- and E-selectin, ICAM-1, VCAM-1 are expressed on endothelial wall to allow leukocyte extravasation. Solubilized circulating forms are detectable in plasma.	VCAM-1 has weak positive associations with HOMA-IR in crude analysis and after adjusting for age, sex, and BMI ($r=0.09$) [78]. In one study of adults, after adjusting for age and sex, only E-selectin was associated with HOMA-IR [79].	No strong evidence of causality for the circulating isoforms. Reasons for cleavage from endothelial wall unclear.	The role of soluble adhesion molecules in human diseases is not clear.
VWF antigen	VWF is released from endothelial wall as a result of vascular dysfunction. Involved in the coagulation cascade.	Moderate positive association with HOMA-IR by quartiles in Framingham Offspring [17]. Weak positive association in older men ($r=0.10$) after adjusting for WC [80].	More likely to be a downstream cause of diabetes complications than to cause IR per se.	VWF also only weakly associated with diabetes risk.

Nutritional factors

Vitamin C	Classical antioxidant vitamin, often reported to limit/reverse oxidative stress.	No strong association with HOMA-IR among adolescents [81].	Mixed evidence from primarily small trials [82].	Meta-analysis of RCTs indicates strong evidence against antioxidant vitamin supplements protecting from risk of mortality.
Vitamin D	"The sunshine vitamin." Has been related to a wide variety of chronic diseases.	No strong association with SI or HOMA-IR comparing those with high and low 25OHD concentrations after adjusting for confounding variables [83].	Insufficient evidence [84].	Large trials of vitamin D supplementation in middle-aged populations are underway. Current meta-analyses cast doubt on benefit of supplementation in chronic disease.

Cardiac biomarkers

ANP/BNP	A-type and B-type natriuretic peptide produced in response to myocardial stretch.	BNP is inversely associated with HOMA-IR in healthy young people [85], although the association is null or positive in older cohorts or those with prevalent disease.	Evidence from MR studies that BNP is causally linked to insulin sensitivity [29].	BNP release from cardiac tissue may therefore function not only to improve vascular function but also to enhance metabolic efficiency.

*Note: r or β values should not be directly compared between studies given differing adjustment models.

EUC, euglycemic-hyperinsulinemic clamp; ISI, insulin sensitivity index; RCT, randomized controlled trial; SI, sensitivity to insulin; WC, waist circumference.

although adjustment for insulin resistance attenuated the association [22]. Second, in older individuals or those with increased vascular risk, high, not low, adiponectin predicted increased risk of cardiovascular disease and mortality [23]. Risk associations are thus highly context dependent.

With respect to causality, a recent Mendelian randomization study did not support a causal role for adiponectin in insulin resistance and T2DM [24]. Furthermore, other data have shown that low adiponectin in humans is more likely to be a downstream signal of hyperinsulinemia, than a causal upstream determinant of insulin resistance [25].

With respect to other adipokines, leptin has also been widely suggested as a cause of insulin resistance, but in most individuals higher leptin is a marker of percent fat mass. Due to the great degree of correlation with fat mass (i.e., information that can be gained from other simple measures of adiposity) it is unlikely to ever be used in clinical practice to predict diabetes. More interesting adipokines are: (i) IL-6, which is also released from fat cells; there is emerging evidence of a causal association of IL-6R with cardiovascular disease [26] and potentially diabetes, and (ii) PAI-1, an inhibitor of fibrinolysis [27]. There is preliminary evidence of a potential causal association with diabetes. Further work on IL-6 and PAI-1 seem warranted.

Endothelial-derived markers and insulin resistance

There is a wealth of data suggesting a potential role for endothelial dysfunction in insulin resistance. Although the direction of causality remains hotly debated, circulating elevations in some endothelial-derived factors, cell adhesion molecules, in particular E-Selectin, ICAM-1, and t-PA have been shown to predict risk for T2DM, independently of other predictors [2]. However, t-PA can also be released from the liver so its link to insulin resistance may be via differential pathways. VWF has also been linked to insulin resistance but more weakly than other parameters. Finally, microalbuminuria is often considered to reflect vascular dysfunction at the level of the kidney and, interestingly, its levels in urine have long been known to be related to insulin resistance in nondiabetic subjects [28].

Cardiac biomarkers and insulin resistance

There is emerging evidence that as well as metabolism impacting cardiac function, cardiac function may also influence metabolism. Natriuretic peptides are produced by the myocardium in response to mechanical stretch as a downstream result of a range of cardiac and vascular pathologies. A-type and B-type natriuretic peptides exert natriuretic and diuretic effects to limit elevation in blood pressure and fluid accumulation. Circulating levels of BNP and its inactive N-terminal metabolite (NT-proBNP) are used for the clinical exclusion of heart failure. However, evidence from genetic studies shows that elevated BNP protects generally healthy people from diabetes [29]. How do natriuretic peptides protect from insulin resistance? There is

evidence that natriuretic peptides cause lipolysis from adipose tissue, and also result in an increase in adiponectin [30]. Thus natriuretic peptides may go some way to "explaining" the adiponectin paradox described earlier; high levels in healthy people are protective, but high levels arising from pathology are adverse signals. Whilst these latter relationships are not commonly discussed in relation to the insulin resistance syndrome, they serve to show that insulin resistance is being linked to some unexpected parameters and in different tissues from those commonly associated with insulin resistance.

Insulin resistance as cardiovascular risk factor?

Given that insulin resistance is associated with dyslipidemia, dysglycemia, high blood pressure, inflammation, thrombotic pathways, and endothelial dysfunction, many have suggested that insulin resistance must be a strong cardiovascular risk factor. Yet, the evidence base for this assumption is relatively limited and there are no large studies linking gold standard clamp-based insulin resistance measurements to subsequent cardiovascular outcomes. The multinational Relationship between Insulin Sensitivity and Cardiovascular disease (RISC) study recently reported weak cross-sectional associations of insulin sensitivity (measured by clamp) with carotid intima media thickness in men but not in women, and insulin sensitivity was not associated with three-year changes in cIMT [31]. To address this important issue, we recently related circulating concentrations of fasting and nonfasting insulin, as well as pro-insulin, to incident coronary heart disease in a meta-analysis of 19 Western prospective studies [32]. The findings showed that in a comparison of individuals who had circulating levels of each of these markers in the top third with those in the bottom third of the population, the odds ratio for CHD was 1.12 (95% CI 0.98–1.28) for raised fasting insulin, 1.35 (1.14–1.60) for raised nonfasting insulin, and 2.23 (1.65–3.00) for raised pro-insulin. These results also suggest that links between CHD risk and fasting or nonfasting insulin levels are likely to be more modest than previously suspected. Powerful genetic data consortia are required to address the causal role of insulin in CVD with confidence. Clearly, this area requires further research but, currently, the best available data do not support hyperinsulinemia as a strong risk factor for vascular disease in people without diabetes.

Other markers and future research

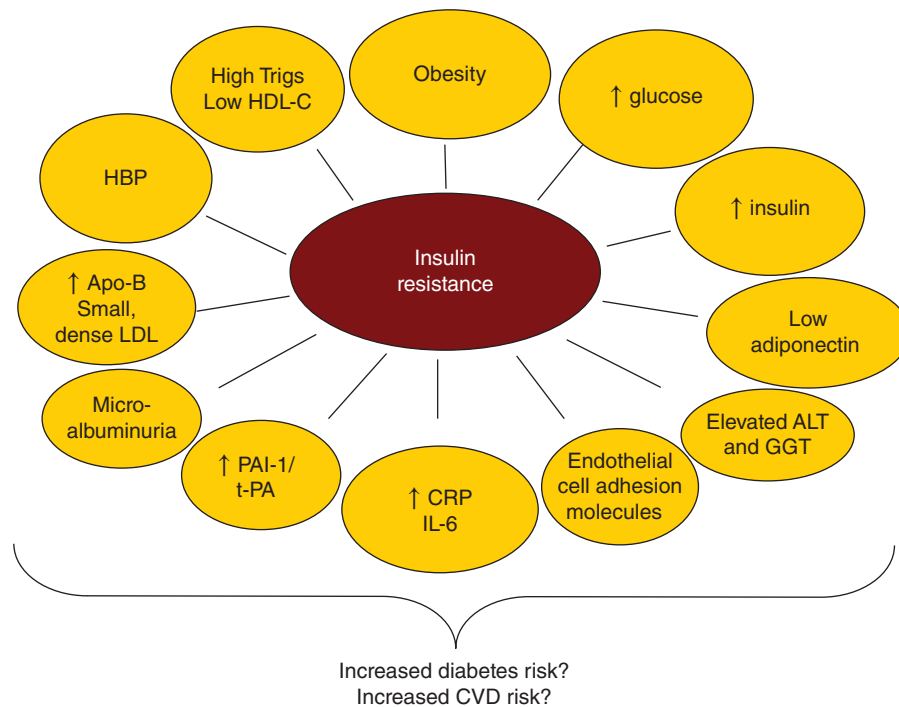
The foregoing observations have detailed the best established risk factors associated with insulin resistance (Figure 23.3) as well some novel emerging risk factors as additionally detailed in Table 23.2, including nutritional measures such as Vitamin D. These are not comprehensive but rather a selection of emerging pathways of interest. Clearly, future research should increasingly harness genetics as well as observational data to better determine causal risk pathways. Similarly, further data are needed to better determine the extent to which insulin resistance is, or is not, linked to cardiovascular risk.


Figure 23.3 Multiple risk factors commonly associated with insulin resistance. This figure shows that numerous risk factors are linked to insulin resistance and since many appear to be related to vascular risk, researchers commonly assume insulin resistance is a strong risk factor for CVD. However, the evidence base, as discussed in the text, is not clear as to how accurate this assumption is.

Introducing insulin resistance to the clinic: the metabolic syndrome

The second section of this chapter now describes how researchers and clinicians have taken commonly measured markers associated with insulin resistance and created risk algorithms which were subsequently tested for clinical utility.

The cluster of commonly measured risk factors for cardiovascular disease and T2DM, which are associated with insulin resistance and are recognized to commonly coexist, have become known as the "metabolic syndrome." The concept of the metabolic syndrome was initially proposed by Reaven who suggested a conceptual framework to link these apparently unrelated clinical and biochemical characteristics [33].

What are the metabolic syndrome criteria?

Features of metabolic syndrome include hypertension, dyslipidemia (specifically hypertriglyceridemia with low HDL-cholesterol), dysglycemia, and central obesity though it should be highlighted that the pathophysiologic basis for the association between these factors remains unidentified. Different national and international organizations have produced various overlapping but different iterations of diagnostic criteria for metabolic syndrome over the last 15 years. Early criteria from the World Health Organization (WHO), International Diabetes Federation (IDF) and National Cholesterol Education Panel (NCEP) for diagnosing metabolic syndrome are listed in Table 23.3 [34–36]. Common to all was the requirement to fulfill three out of five criteria but not all stipulated an essential criterion. For example, WHO metabolic syndrome [36] criteria required the presence of some biochemical evidence of insulin resistance or dysglycemia, to which other characteristics were then added. By contrast, IDF criteria [35] required evidence of central obesity while NCEP ATP III criteria made no such stipulation. Therefore, WHO criteria were most directly linked with Reaven's proposed, but still unexplained, observation linking insulin resistance with hypertension and dyslipidemia as an explanation for the excess cardiovascular risk in diabetic patients. One immediate practical difficulty was the fact that fasting insulin levels were seldom measured in a routine clinical setting and that a definitive insulin resistance diagnosis was poorly defined. Therefore the change in focus of the IDF criteria to central obesity rendered these criteria not only easier to assess, but also raised awareness of obesity as being a key player in the majority at risk of developing T2DM. The IDF and NCEP criteria were also very easily applied to many existing large epidemiologic studies, leading to the publication of huge swathes of epidemiologic research of variable quality over the last two decades exploring the clinical utility of metabolic syndrome. Importantly, the availability of various criteria for identifying metabolic syndrome and the knowledge that the relationship between risk of cardiometabolic disease and central

Table 23.3 World Health Organization (WHO), International Diabetes Federation (IDF) and National Cholesterol Education Panel (NCEP) criteria for diagnosing metabolic syndrome

	WHO (modified) criteria [36]	IDF criteria [35]	NCEP criteria [34]
Essential criterion	Fasting hyperinsulinemia (highest 25% of nondiabetic population), or Type 2 diabetes mellitus, or Impaired glucose tolerance, or Fasting plasma glucose $\geq$6.1 mmol L^{-1}	Men $\geq$94 cm or women $\geq$80 cm (Europoid) or sex- and ethnicity-specific elevated waist circumference.	–
	Plus at least two of:	*Plus at least two of:*	*At least three of:*
Central obesity	BMI >30 kg m^{-2} or waist:hip ratio >0.90	–	Men >102 or women >88 cm waist circumference
Fasting plasma glucose (fasting)	–	$\geq$5.6 mmol L^{-1} or previously diagnosed type 2 diabetes	$\geq$6.1 mmol L^{-1}
Blood pressure	$\geq$140/90 mmHg or on therapy	$\geq$130/85 mmHg or on therapy	$\geq$130/85 mmHg or on therapy
Triglycerides (fasting)	$\geq$2.0 mmol L^{-1}	$\geq$1.7 mmol L^{-1} or receiving specific therapy	$\geq$1.7 mmol L^{-1}
HDL-cholesterol	<1.0 mmol L^{-1}	Men <1.04 mmol L^{-1}, Women <1.29 mmol L^{-1} or receiving specific therapy	Men <1.04 mmol L^{-1}, Women <1.29 mmol L^{-1}
Other	Microalbuminuria	–	–

obesity varies according to ethnic group led to confusion in clinical practice and controversy in published literature, though controversy has not been limited to this specific issue. To address recognized shortcomings, a harmonized set of criteria was produced by a working group on behalf of the International Diabetes Federation Task Force on Epidemiology and Prevention, the National Heart, Lung, and Blood Institute, the American Heart Association, the World Heart Federation, the International Atherosclerosis Society, and the International Association for the Study of Obesity in 2009 [37] (see Table 23.4). As in previous criteria, three out of five criteria are now required to be identified as having metabolic syndrome. However, the presence of central obesity as an essential criterion was removed with the result that the presence of any three criteria now constitutes a diagnosis of metabolic syndrome. Furthermore, flexibility has been introduced into the definition of metabolic syndrome as population- and country-specific definitions for elevated waist circumference are required, reflecting the understandable lack of agreement on how best to record and define central obesity. Suggested current thresholds for elevated waist circumference, as recommended by various organizations, are provided in the document (see also Table 23.5). The authors propose that further research is required to properly delineate the relationship between waist circumference and cardiometabolic risk in all ethnic groups and suggest that particular health systems may even base the choice of waist circumference threshold on local considerations, including healthcare funding.

Table 23.4 Harmonized criteria for identifying metabolic syndrome

Measure	Categorical thresholds
Elevated waist circumference	Population- and country-specific definitions
Elevated triglycerides	$\geq$1.7 mmol L^{-1} or drug therapy for hypertriglyceridemia
Reduced HDL-cholesterol	<1.0 mmol L^{-1} in men, <1.3 mmol L^{-1} in women or drug therapy for low HDL-cholesterol
Elevated blood pressure	Systolic $\geq$130 mmHg and/or diastolic $\geq$85 mmHg or drug therapy with a history of hypertension
Elevated fasting plasma glucose	$\geq$5.6 mmol L^{-1} or glucose-lowering therapy

The purpose of the metabolic syndrome concept

The purpose behind introduction of the metabolic syndrome into clinical practice and published epidemiologic research appears to have been the desire to facilitate identification of those at risk of experiencing a cardiovascular event and/or developing T2DM in the medium to long term using a simple tool. Rationale for using metabolic syndrome has been summarized as: (i) facilitating research into a possible unifying pathophysiologic explanation for these strongly associated

Table 23.5 Recommended waist circumference thresholds for abdominal obesity by organization

Population	Organization	Recommended waist circumference threshold for abdominal obesity	
		Men	*Women*
Europoid	IDF	≥94 cm	≥80 cm
Caucasian	WHO	≥94 cm (increased risk)	≥90 cm (increased risk)
		≥102 cm (still higher risk)	≥88 cm (still higher risk)
United States	NCEP ATP III	≥102 cm	≥88 cm
Canada	Health Canada	≥102 cm	≥88 cm
European	European Cardiovascular Societies	≥102 cm	≥88 cm
Asian (including Japan)	IDF	≥90 cm	≥80 cm
Asian	WHO	≥90 cm	≥80 cm
Japanese	Japanese Obesity Society	≥85 cm	≥90 cm
China	Co-operative Task Force	≥85 cm	≥80 cm
Middle East, Mediterranean	IDF	≥94 cm	≥80 cm
Sub-Saharan Africa	IDF	≥94 cm	≥80 cm
Ethnic Central and South American	IDF	≥90 cm	≥80 cm

risk factors, (ii) quantifying chronic disease risk and allowing between-country comparison, (iii) guiding clinical management decisions, and (iv) providing an easily understood public health message [38]. Those involved in developing and promoting the concept of the metabolic syndrome have described it as a potentially valuable global public health tool with the ability to identify high-risk individuals at a young age. Undoubtedly, one positive effect of the adoption of the term has been to familiarize healthcare professionals with the potentially deleterious effects of obesity and to provide an easily understood term, or clinical label, to describe a commonly encountered type of patient. Furthermore, appreciation of those with metabolic syndrome has likely raised the profile of lifestyle advice and increased the provision of advice to those at risk of developing diabetes.

The clinical utility of metabolic syndrome has been controversial, however, with proponents arguing that identifying a patient with metabolic syndrome is a simple and effective method to identify someone at potentially long-term risk of cardiometabolic risk [39] but with skeptics arguing that the label of "metabolic syndrome" adds little to established methods for risk calculation for cardiovascular disease and T2DM [40–42]. Some key topics of debate have been the presence of various differing sets of criteria, now addressed by the introduction of the harmonized criteria already referred to, and the fundamental question of the role and value of metabolic syndrome in clinical practice. It is this latter point that remains unresolved. Some of the more humorous and incisive pieces in the medical literature in recent years have addressed this matter [43–45].

Since the introduction of the Framingham Risk Score (based on classical cardiovascular risk factors namely hypercholesterolemia, hypertension, smoking), supplemented more recently with ever better performing risk scores in the United Kingdom such as QRISK2 [46] and ASSIGN [47] which incorporate additional risk factors like family history and social deprivation, clinicians have had at their disposal effective tools for prediction of cardiovascular events thereby facilitating allocation of effective risk-lowering therapies to those at highest risk. The presence of metabolic syndrome is itself unequivocally associated with increased risk of cardiovascular disease, as confirmed in various studies [48–50], but this is unsurprising given that it includes some powerful cardiovascular risk factors, namely hypertension and low HDL-cholesterol. In the view of many, the key question has therefore been whether identifying a patient as having metabolic syndrome yields additional predictive information on top of these risk scores. In other words, to be of clinical value, any new risk predictor must be more effective than current risk predictors to demonstrate clinical utility. It has now been well demonstrated that identification of metabolic syndrome cannot compete with the cardiovascular predictive capabilities of established cardiovascular risk scores and also that it adds minimal incremental information [51–53]. This apparent under-performance is unavoidable given the necessary absence of three of the strongest known cardiovascular risk factors namely age, low-density lipoprotein (LDL) cholesterol, and smoking status. To illustrate this problem with a clinical example, two theoretical but commonly encountered patients are listed in Table 23.6 (as previously described [42]).

Table 23.6 Hypothetical example of cardiovascular risk in two individuals, one with and one without metabolic syndrome

	Mr. A	Mr. B
Waist circumference (cm)	105	80
Triglyceride (mmol L^{-1})	2.2	1.3
HDL-cholesterol (mmol L^{-1})	0.9	1.2
Fasting plasma glucose (mmol L^{-1})	6.2	5.0
Blood pressure (mmHg)	145/90	145/90
Age (years)	40	60
Smoking status	No	Yes
LDL-cholesterol (mmol L^{-1})	3.0	6.0
Metabolic syndrome	Yes (5/5 criteria)	No (1/5 criteria)
Framingham risk score (%)	8	42

Although both are hypertensive, only Mr. A fulfills all criteria for metabolic syndrome (5/5), unlike Mr. B. Nonetheless, Mr. B is at considerably greater risk of vascular disease due to his older age, his higher LDL-cholesterol, and his smoking status. In addition, individual components of the metabolic syndrome often outperform the overall metabolic syndrome unlike established cardiovascular risk scores [54–56].

Where metabolic syndrome arguably makes a stronger case for routine clinical use is in the prediction of developing T2DM, as demonstrated in previous epidemiologic studies [49,57] and in keeping with Reaven's proposed unifying hypothesis, insulin resistance. Three of the five variables in the metabolic syndrome criteria are more strongly linked to diabetes than cardiovascular disease, namely elevated triglycerides, central obesity, and dysglycemia. As an example, the Emerging Risk Factors Collaboration's (ERFC) comprehensive analysis established that impaired fasting glycemia is only weakly associated with incident cardiovascular events [58]. By contrast, IFG's association is an order of magnitude more powerful with risk of developing diabetes than with risk of cardiovascular disease [59]. The cases of BMI and hypertriglyceridemia are analogous. Regardless, knowledge of an individual's fasting blood glucose provides at least the same predictive information as knowledge of metabolic syndrome status for identifying those most likely to develop T2DM.

Statistical considerations and other issues

When designing any risk scoring system, those proposing such a score must weigh up various competing factors. Metabolic syndrome benefits from the inclusion of clear (and now unambiguous, with the exception of waist circumference) criteria. However equal weighting is given to the five criteria while it is known that they do not contribute equally to the development of cardiometabolic disease. As noted above, two of the five criteria are strongly linked to cardiovascular disease but only weakly to risk of developing diabetes. The converse is true of the other three variables. Secondly, consideration of any biomarker as a continuous variable adds predictive power while

dichotomization of data limits power substantially. One component, serum triglycerides, has a moderately high within-subject biologic variability of 20% with the result that classification of individuals with triglyceride levels close to 1.7 mmol L^{-1} may give different results from day to day [60]. Other potential weaknesses include the reliance on fasting samples while there is a move towards using nonfasting sampling for both diabetes (HbA1c) and cardiovascular (lipids, HbA1c) risk estimation and diagnosis. Some also challenge the inclusion of those with established T2DM and/or cardiovascular disease in the metabolic syndrome based on the assertion that it adds little to their clinical management [38,40]. Finally, metabolic syndrome describes relative risk of cardiometabolic disease and not absolute risk.

Treatment of patients with features of the metabolic syndrome

The prevalence of individuals with the metabolic syndrome or components thereof is undeniably high and constantly increasing. Despite control of major cardiovascular risk factors such as LDL-cholesterol, blood pressure, and smoking, a combination of factors regularly leads to a failure to address obesity or improve glycemic control with a resultant residual higher cardiovascular risk than is observed in the normal population. Therefore, attention must be focused on what additional approaches can be brought to bear to reduce this residual risk. While an in-depth discussion of outcome trial data regarding drugs aimed at lowering triglycerides or increasing HDL-cholesterol is beyond the scope of this chapter, their results can be summarized as disappointing thus far. Whether we should target the hypothesized upstream insulin resistance, and if so with what tools, remains unproven for reducing cardiovascular risk. Those with impaired fasting glycemia and impaired glucose tolerance are not routinely prescribed glucose-lowering agents although cardiovascular endpoint trials of relevant therapies such as metformin are either underway or in feasibility studies. Lifestyle modification is commonly recommended and has been shown to reduce the development of T2DM in those at risk [61,62], but data supporting a reduction in cardiovascular outcomes remains elusive. Problematically, while intensive lifestyle advice can be provided in the context of a clinical trial, significant improvement remains difficult to achieve and sustain outside the research environment. Large observational studies of weight loss surgery strongly suggest a reduction in risk of developing diabetes [63] but access to such procedures is necessarily limited to a subset of the population based on availability of resources.

Current thinking regarding metabolic syndrome

In November 2008, a WHO Expert Consultation was undertaken to evaluate the utility of the concept of metabolic

syndrome in four areas: pathophysiology, epidemiology, clinical work, and public health [38]. Much of the ground addressed in the report of the consultation is covered in the earlier sections of this chapter. The consultation's conclusions are ones which the authors of this chapter are in agreement with. They made the simple but important observation that while metabolic syndrome has gained traction as a widely recognized concept, a formal diagnosis of metabolic syndrome is seldom made and the condition is rarely included in guidelines for the treatment and prevention of cardiometabolic disease. The group rightly called for a halt to studies comparing different versions of the metabolic syndrome and also emphasized that research should be focused on identifying the mechanism or mechanisms underlying the clustering of metabolic risk factors, rather than attempting to further refine diagnostic criteria. The main conclusion was therefore that while metabolic syndrome represents a useful educational concept, it has limited practical utility as a diagnostic or management tool.

Conclusion

The terms "insulin resistance syndrome" or "metabolic syndrome" are widely used in clinical research but their precise definitions remain weakly defined and their clinical utility questionable. The present chapter has summarized numerous biomarkers associated with insulin resistance and attempted, where possible, to determine which may be causally linked to insulin resistance, and the directionality of such links. A minority of insulin resistance-associated risk factor perturbations (e.g. those related to NAFLD or PCOS) appear relevant to clinical practice whereas simple risk factors (age, gender, obesity, family history, and ethnic origin) predict type 2 diabetes well. Novel blood-based insulin resistance biomarkers seem unable to meaningfully (or cost-effectively) improve diabetes prediction. In terms of vascular disease, and contrary to popular belief, the current data do not support a strong association of insulin resistance (in the absence of diabetes) with cardiovascular disease and, similarly, metabolic syndrome criteria do not improve prediction beyond simpler nonfasting cardiovascular risk scores.

CHAPTER 24

β-Cell mass and function in human type 2 diabetes

Piero Marchetti[1] and Ele Ferrannini[2]
[1]Department of Endocrinology, University of Pisa, Pisa, Italy
[2]Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy

Key points

- β-Cell mass is reduced by 30–40% in type 2 diabetes, with a wide overlap with nondiabetic subjects.
- Both enhanced apoptosis and abnormal autophagy account for β-cell demise.
- Relative excess of α cells, architectural disarray, and reduced connectivity are additional features of diabetic islets.
- Cultured human β-cells from diabetic patients respond to glucose poorly as do β-cells from nondiabetic donors exposed to *in vitro* hyperglycemia.
- *In vivo*, impaired β-cell glucose sensing and incretin-mediated secretory potentiation contribute to dysglycemia quantitatively.
- Functional incompetence dominates over β-cell loss in the pathogenesis of diabetes and prediabetes.
- A variable but clinically significant proportion of β-cell dysfunction is reversible.

Introduction

Insulin-producing β-cells are the predominant endocrine cell type in pancreatic islets, comprising 50–80% of islet cells [1–3]. Studies with autoptic samples, organ donor specimens, and surgical cases have found that β-cell mass in the human pancreas may vary from 0.6 to 2.1 g, with β-cell volume and area (relative to the pancreatic tissue) ranging from 1.1–2.6% and 0.6–1.6%, respectively [4–15]. Islet insulin content has been reported to be 100–500 μU per islet [16–20], but some islets may contain more than 1000 μU insulin [20]. As islet number in adult subjects also varies widely (0.5–4 million per pancreas) [21], pancreatic insulin content, as measured in a few studies, shows a marked intersubject variability (up to 10-fold) [7,17].

Functionally, β-cells are the most sophisticated of endocrine cells. Insulin must be supplied to body tissues in amounts, time-dynamics and flexibility able to maintain plasma glucose within a narrow concentration interval on a minute-by-minute basis [22–25]. In fact, insulin secretion must cope with acute (meals, exercise, stressful events) and long-term (body weight gain or loss, aging, pregnancy) changes. Whereas the amount of insulin released daily has been reported to range ∼20–70 U (mainly depending on body weight) [26,27], capturing the multifaceted features of insulin secretion *in vivo* is a difficult task [28–30]. However, the recent use of human islets isolated from the pancreas of organ donors has allowed the direct study of β-cell insulin release under different conditions, showing that several of the insulin secretion properties observed *in vivo* (dynamics, oscillatory pattern, metabolic and/or pharmacologic perturbations) can be reproduced *ex vivo* [18,31–37]. In this chapter, we will summarize available knowledge on the quantitative and functional differences between nondiabetic and T2DM β-cells, showing that β-cell loss and changes in β-cell secretory phenotype could have a different impact on the onset and progression of type 2 diabetes (T2DM).

β-Cell mass in type 2 diabetes

Although quantification of β-cells in the human pancreas is a difficult task, morphometric analyses have been performed by several authors to assess β-cell mass (when the weight of pancreas specimens was available), volume (usually assuming that the islets are spherical), and/or area (insulin-positive proportions in the islets or the pancreatic tissue) [4–7,9,10,12–15,38–46]. The amount of β-cells has been usually (although not always) reported to be significantly reduced in the pancreata of patients with T2DM; Table 24.1 summarizes most of the available data. Early work reported that total islet number was 30–50% lower in histology samples from type 2 diabetic subjects as compared to nondiabetic individuals [38,39]. A reduction of total islet volume in diabetic verus nondiabetic pancreata was also shown [40,41], which became

Table 24.1 β-Cell morphometric data (type 2 diabetic or "prediabetic" vs. nondiabetic cases) as available from articles retrievable from PubMed (www.ncbi.nlm.nih.gov/pubmed, accessed July 31, 2014)

more marked when accounting for the presence of amyloid [40]. In the following years, although a few authors were not able to find major differences in β-cell amount in diabetic compared to nondiabetic pancreas specimens [42–44], several studies consistently showed that β-cell quantity is reduced in T2DM. Clark and colleagues reported a 24% reduction in β-cell area in their series of type 2 diabetic pancreas samples [45], and islet β-cell volume and total β-cell mass were found to be significantly lower (∼30%) in specimens from Japanese type 2 diabetic patients than in samples from nondiabetic individuals [4]. Similarly, a study conducted in Korea with pancreatic samples from organ donors or following surgical removal found that β-cell volume was approximately 25% reduced in T2DM [5]. Pancreatic autoptic samples from type 2 diabetic patients, subjects with impaired fasting glycemia, and nondiabetic individuals have also been studied (the groups were subdivided into lean or obese based on BMI) [6]. Obese subjects with IFG or diabetes had a 40–60% reduction in β-cell volume in comparison to BMI-matched, nondiabetic cases. In the nonobese group, diabetes was associated with 41% reduction of β-cell volume. In a more recent study [7], the authors analyzed autoptic samples from 57 type 2 diabetic and 52 nondiabetic European subjects, confirming that β-cell mass is lower (35% on average) in the diabetic cases (Figure 24.1). Similarly, when a comparison was made of pancreata obtained from lean and obese (BMI > 27 kg m^{-2}) diabetic and nondiabetic cadaveric donors [9], it was found that β-cell volume and mass were reduced by approximately 35% in the obese type 2 diabetic cases; however, β-cell amount in lean donors was unaffected by the presence of diabetes [9]. Additional
Figure 24.1 β-cell mass is significantly decreased in type 2 diabetic patients as compared to nondiabetic individuals; note the large intersubject variability and wide overlap between the two groups. Source: Adapted from Rahier et al. 2008 [7]. Reproduced with permission of John Wiley.

information from later studies indicates that β-cell loss in T2DM may preferentially involve larger islets (in particular when located in the head of the pancreas) [10,13], confirms the potential role of amyloid deposition [46] and the presence of β-cell reduction in prediabetes [14], and suggests that the use of incretins may be associated with changes in β-cell amount [12].

Interestingly, however, a study carried out with the combined use of light and electron microscopy [15] suggested that the loss of β-cells in T2DM as assessed by insulin staining may be overestimated because of degranulation. In summary, the amount of β-cells appears to be reduced in human T2DM, especially in patients with long-standing disease [7]; further work is needed to more precisely quantify the prevalence, time-course and circumstances of β-cell loss.

The role of β-cell death and regeneration

The loss of β-cells in T2DM has been mainly attributed to increased β-cell death due to apoptosis and other forms of cell death [6,9,13,46–49], possibly driven by adverse environmental conditions [50–52] and probably mediated by several intracellular mechanisms [50–54]. Apoptosis is a type of programmed cell death morphologically characterized by cell rounding up, bleb formation and chromatin condensation (Figures 24.2(a) and 24.2(b)). As a matter of fact, in autoptic pancreatic samples apoptosis has been shown to be significantly increased in both obese and lean type 2 diabetic cases as compared to BMI-matched, nondiabetic controls [6]. In another study, β-cell apoptosis was found to be threefold increased in obese type 2 diabetic patients [9], although the diabetic condition did not affect apoptosis in lean individuals. Increased β-cell apoptosis in diabetic islets has been confirmed by electron microscopy [47]. In addition, by assessing cytoplasmic histone-associated DNA fragments, it has been observed that islet cell death is significantly enhanced in isolated diabetic islets [18]. These changes are accompanied by increased numbers of cells positive for activated caspase-3 [48] as well as greater activity of caspase-3 and caspase-8 [18], which are key molecules in the induction and execution of apoptosis.

However, forms of programmed cell death other than apoptosis have been described [49]. One involves autophagy, which is a type of cell death that occurs without marked chromatin condensation and is accompanied by massive vacuolization of the cytoplasm [55–57]. In general, normally functioning autophagy has a beneficial role for cells (including the β-cell [58–60]) as it regulates the turnover of aged proteins and eliminates damaged structures and organelles [60]. However, cells that undergo altered autophagy may die in a nonapoptotic manner [55–57]. The presence of autophagy was investigated in β-cells from T2DM and matched nondiabetic subjects [49]. On electron microscopy, there were significantly more dead β-cells in diabetic than control samples; while several of these cells had morphologic signs of apoptosis, massive vacuole overload (suggesting altered autophagy) was associated with a proportion of dead β-cells without signs of apoptosis (Figure 24.2(c)). This proportion was significantly higher in type 2 diabetic samples. It can be therefore concluded that β-cell death is increased in type 2 diabetic patients due to enhanced apoptosis and other forms of cell death, which may contribute to β-cell failure in this disease.

Whether defects of β-cell regeneration also plays a role in the reduction of β-cells in human T2DM is still unclear. β-cell regeneration may essentially occur by replication (proliferation) of existing cells, neogenesis from precursors or transdifferentiation of existing mature cells [61–67]. Normally, insulin-positive cells appear in the human pancreas at around the 8th week of gestation; at 10 weeks postconception all clusters containing more than 10 insulin-positive cells have developed a close relationship with vascular structures [68]. After an additional 2–3 weeks, human fetal islets contain cells independently immunoreactive for insulin, glucagon, somatostatin and pancreatic polypeptide [68]. During prenatal pancreas development, there is a linear increase in fractional β-cell area, which reaches a value of ~3% at birth [69]. β-cell proliferation is very efficient during fetal life, involving more than 3% of β-cells during week 17–32 of gestation [69,70]; this proportion then tends to decrease and approximates 1.5–2.0% at birth [69,70]. After birth, as shown by the study of autoptic pancreatic samples from subjects aged 2 to 20 years, β-cell mass expands several-fold from infancy to adulthood, mainly due to growth in islet size rather than number, a process driven by the rate of β-cell replication [21]. After the age of 20–30 years, however, the rate of islet β-cell replication seems negligible, as shown in two independent studies analyzing lipofuscin accumulation and thymidine incorporation in human β-cells [71,72]. Both these studies concluded that, in human islets, the

β-cell complement is fully established by the age of 20–30 years. This implies that β-cell regeneration in adults may occur at a very low rate, if at all.

Nevertheless, β-cell mass in adult human individuals can increase, such as occurs in obesity and during pregnancy [5–7,9,73,74]. In one of the studies mentioned earlier [6], it was observed that nondiabetic obese subjects (with an average BMI of $\sim35\,kg\,m^{-2}$) show a 50% increase in β-cell volume as compared to nondiabetic lean subjects (average BMI of $\sim23\,kg\,m^{-2}$). Apoptosis and replication did not differ significantly between obese and nonobese cases, and the increase of β-cells was attributed to enhanced neogenesis, as indirectly suggested by the greater number of insulin positive cells in or close to the ducts [6]. However, the same authors, in a more focused article, while confirming the augmented β-cell mass in autoptic pancreatic samples of obese subjects, were unable to find differences in terms of apoptosis or regeneration, as assessed by some of the currently available surrogate markers (Ki67, insulin-positive cells in the duct wall) [73]. In another report [9], obesity (average BMI of $31\,kg\,m^{-2}$) was associated with a twofold increase in β-cell volume compared to lean (average BMI of $24\,kg\,m^{-2}$) nondiabetic individuals. In this case, the authors found that both β-cell replication and neogenesis were significantly enhanced in the obese samples in the face of similar rates of apoptosis.

Pregnancy is also associated with greater β-cell mass [75]. Although, for obvious reasons, data in humans are very scanty, one study has reported on the morphometry of the pancreatic islets during gestation in humans [74]. The authors collected pancreases obtained at autopsy from women who had died while pregnant, and found that the pancreatic fractional β-cell area was increased by approximately 1.4-fold compared to nonpregnant women [74]. Mean β-cell size was not different, and in pregnancy there were more small islets rather than an increase in islet size or β-cells per islet. No increase in β-cell replication or change in β-cell apoptosis was detected, but duct cells positive for insulin and scattered β-cells were increased with pregnancy, again suggesting, although indirectly, a possible preminent role of β-cell neogenesis. Interestingly, in a case of gestational diabetes it has been observed that total insulin area was reduced, not due to increased apoptosis but reduced regeneration [76].

The issue of β-cell regeneration has been investigated in a few morphometric studies with pancreases from nondiabetic and type 2 diabetic individuals (Table 24.2). It was initially reported that there was no significant difference in the frequency of β-cell replication (as assessed by Ki67 protein staining) between obese nondiabetic and type 2 diabetic subjects or lean nondiabetic and type 2 diabetic subjects [6]. Similarly, when neogenesis was indirectly quantified by counting duct cells immunoreactive for insulin, no difference was found between the obese or lean nondiabetic and type 2 diabetic cases [6]. However, in another report slightly different results were obtained [9]. When β-cell replication was examined by proliferating cell nuclear antigen (PCNA) staining, this was lower in obese type 2 diabetic than in weight-matched nondiabetic cases; on the other hand, a "neogenic" index calculated from the amount of insulin positive cells or small clusters in the duct walls and/or the acinar tissue was found to be similarly increased in nondiabetic obese individuals and in obese or lean type 2 diabetic patients as compared to nondiabetic lean subjects [9]. Three additional studies were published thereafter [12,14,46], all showing no difference between diabetic and nondiabetic samples in the number of cells co-stained for insulin and Ki67; however, in one report the prevalence of insulin-positive cells in the duct walls was found to be significantly higher in subjects with impaired glucose tolerance and significantly lower in those with T2DM, compared to nondiabetic cases [14].

Altogether, the available information, obtained with the use of surrogate markers and indexes of regeneration, indicates

Table 24.2 Summary of data on β-cell regeneration (type 2 diabetic or "prediabetic" vs. nondiabetic cases) as available from articles retrievable from PubMed (www.ncbi.nlm.nih.gov/pubmed, accessed July 31, 2014)

Authors	Journal and year (reference in this chapter)	Main results
Butler AE, et al.	*Diabetes*, 2003 [6]	No difference in the number of cells double positive for insulin and Ki67 between nondiabetic subjects (ND) and individuals with type 2 diabetes (T2DM); no difference in the proportion of insulin-positive cells in the duct walls between ND and T2DM
Hanley SC, et al.	*Endocrinology*, 2010 [9]	Number of cells double positive for insulin and Ki67 significantly lower in obese T2DM vs. obese ND; "neogenic" index (based on insulin-positive cells/clusters in the duct walls or the acinar tissue) significantly higher in lean T2DM vs. lean ND
Jurgens AC, et al.	*Am J Pathol*, 2011 [46]	No difference in the number of cells double positive for insulin and Ki67 between ND and T2DM
Butler AE, et al.	*Diabetes*, 2013 [12]	No difference in the number of cells double positive for insulin and Ki67 between ND and T2DM; no difference in the proportion of insulin-positive cells in the duct walls between ND and T2DM
Yoneda S, et al.	*JCEM*, 2013 [14]	No difference in the number of cells double positive for insulin and Ki67 between ND and individuals with IGT or T2DM; prevalence of insulin-positive cells in the duct walls significantly higher in subjects with IGT and significantly lower in those with T2DM, compared to ND

that β-cell replication does not seem to differ between type 2 diabetic and nondiabetic β-cells, whereas neogenesis may or may not be reduced in T2DM. Clearly, even if present, in T2DM β-cell regeneration is not sufficient to replace the β-cells that have been demised.

The dominance of β-cell functional impairment

As discussed earlier, the available evidence indicates that an average 30% loss of β-cells is present in the islets of patients with T2DM. However, based on a series of considerations it is unlikely that this β-cell deficit alone is the cause of most cases of diabetes. First, *in vivo* assessment of β-cell function consistently shows a >50% reduction in patients with overt T2DM as compared to nondiabetic subjects, a difference that is amplified when using intravenous glucose [27,77,78] (Figure 24.3). Thus, when β-cell function is indexed as β-cell glucose sensitivity (i.e., the slope of the insulin secretion/plasma glucose dose–response [79], type 2 diabetic patients show a marked inability to respond to changing glucose levels with a prompt rise in insulin release; this deficiency is accentuated in the presence of severe fasting hyperglycemia [80] (Figure 24.4). Of note, while β-cell mass estimates in type 2 diabetic patients overlap with those of nondiabetic subjects widely, the distribution of β-cell functional indices is well separated between type 2 patients and controls (Figure 24.5). It is therefore quantitatively incongruous that a deficit in β-cell mass can be the sole cause of the functional impairment. Secondly, in pancreatectomized patients and in subjects who undergo partial pancreas removal for the purpose of living organ donation, diabetes tends to develop more frequently over the years when β-cell mass declines by more
Figure 24.4 Plots of insulin secretion rates against concomitant plasma glucose levels in subjects with normal glucose tolerance (NGT), impaired glucose tolerance (IGT), and type 2 diabetes (T2D, by quartile of fasting hyperglycemia). The mean slope of the fitting functions measures β-cell glucose sensitivity. Source: Redrawn from Ferrannini 2005 [80].

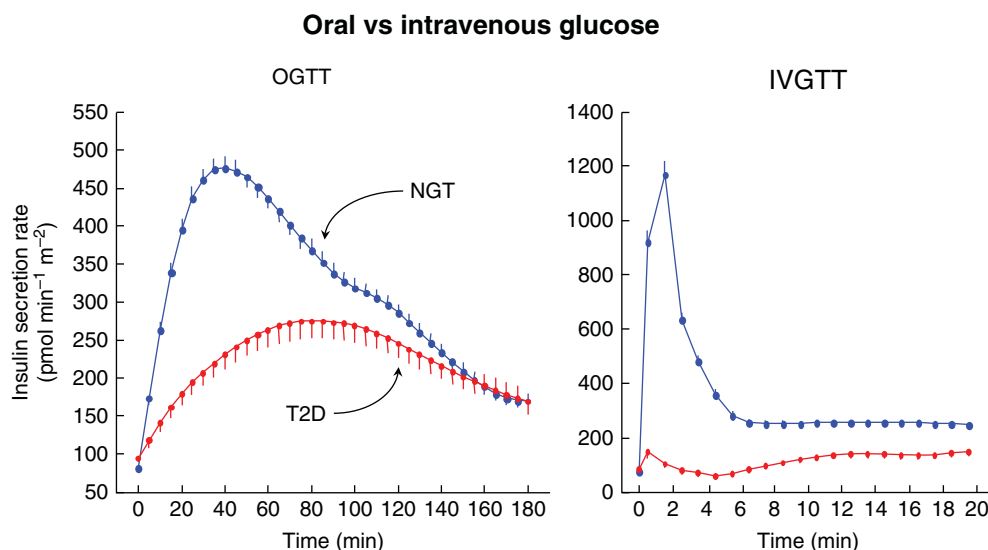
than 50% [81–84]. Thirdly, bariatric surgery is followed by long-lasting resolution of diabetes in a high proportion of type 2 diabetic subjects, in some cases with full recovery of β-cell functional properties [85–87] (Figure 24.6). Finally, it has been clearly shown that any treatment resulting in amelioration of glycemic control is associated with partial reversal of β-cell dysfunction [88–90]. All this is in line with the findings of detailed morphometric studies, showing a very large variability in islet mass, with a wide overlap between nondiabetic and type 2 diabetic individuals [7] (Figure 24.1). Moreover, studies done in parallel with light and electron microscopy have shown that a proportion of β-cells might not be evidentiated by insulin immunostaining, due to low content of insulin granules, indicating the presence of living, but functionally incompetent


Figure 24.3 Insulin secretory response to oral (OGTT) and intravenous glucose (IVGTT) in subjects with normal glucose tolerance (NGT) or type 2 diabetes (T2D). Redrawn from [78]. Note the flat insulin response to intravenous but not oral glucose in T2D.

β-cell mass vs β-cell function
Figure 24.5 Comparison of β-cell mass and β-cell function. β-Cell mass—estimated in autoptic samples from nondiabetic and type 2 diabetic donors—shows a wide overlap between the two groups. Source: Adapted from [7]. By contrast, β-cell function—indexed as β-cell glucose sensitivity from mathematical modeling of OGTT data—shows very limited overlap between diabetic and nondiabetic subjects within the same BMI intervals. Source: Ferrannini 2005 [80].

β-cell function after bariatric surgery

β-cells [15]. As a consequence, β-cell secretory dysfunction is the dominant defect in the majority of diabetic patients.

This point can also be addressed by studying isolated human islets, which under certain circumstances can be prepared from the pancreas of organ donors (Figure 24.7) [91–93]. Although initial work was not able to show differences in insulin secretion between nondiabetic and type 2 diabetic islets [94,95], studies over the last 2–3 decades have consistently demonstrated defects of insulin release from type 2 human diabetes islets [18,36,96–98]. In a report published in 1994, it was shown that the release of insulin evoked by glucose was lower in type 2 diabetic than in nondiabetic islets [96]. However, the secretory

response to a combination of L-leucine and L-glutamine appeared less severely altered [96]. In a more recent study, islets isolated from eight diabetic and nine nondiabetic donors were evaluated by *in vitro* islet perifusion experiments [98]. Basal insulin secretion was similar between normal and diabetic islets. However, the islets from diabetic donors released less total insulin in response to increasing glucose levels and also exhibited a higher threshold for the initiation of insulin secretion (Figure 24.8). In addition, an equivalent amount of type 2 diabetic islets did not fully correct hyperglycemia when transplanted into diabetic mice in comparison with normal islets [98]. In another study, when insulin secretion was

measured in response to glucose, glibenclamide, and arginine in isolated nondiabetic and type 2 diabetic islets, again no significant difference in insulin release in response to 3.3 mmol L^{-1} glucose was observed [36]. However, when challenged with 16.7 mmol L^{-1} glucose, diabetic islets secreted significantly less insulin than nondiabetic islets. Insulin secretion during glibenclamide and arginine stimulation was also lower from diabetic islets than from control islets; of note, in this series type 2 diabetic islets released more insulin in response to non-glucose stimuli than in response to glucose. Interestingly, similar changes in insulin secretion can be induced in nondiabetic human islets by prolonged exposure to increased levels of free fatty acids (in particular, palmitate) or glucose [31,99–102], mimicking findings reported in *in vivo* studies [103,104]. All these data clearly indicate that type 2 diabetic β-cells have defective insulin secretory behavior, which contributes to the development of hyperglycemia at least in part independently of β-cell mass.

Disruption of β-cell dialogue in the islet

It has long been recognized that β-cells dialogue with each other and with the other islet endocrine cells, mainly through autocrine and paracrine communication [105–111]. This is made possible by the peculiar organization of endocrine cells in human islets [3,112]—allowing more than 70% of β-cells to be in contact with non-β-cells [112]—and the abundance of gap junctions (containing connexin proteins) and other cell–cell adhesion complexes [109,113–115]. In addition, endocrine cells could influence one another by the action of the respective hormones via intra-islet blood flow [116,117]. Finally, nonhormonal endocrine cell products (such as ATP and zinc) and neurotransmitters (released either by islet cells or by sympathetic and parasympathetic nerve fibers) influence β-cell function [109–111]. Disruption of these multiple levels of β-cell dialogue in human T2DM has been hypothesized. A well-known feature of T2DM is hyperglucagonemia [118–121], but studies on the relative role of α-cell number and function have given conflicting results. Deng et al. [34] found that the proportion of glucagon-containing cells was significantly increased (52 vs. 35%) in their 14 type 2 diabetic as compared to 14 nondiabetic organ donor pancreases, whereas *ex vivo* glucagon release in isolated islet perifusion studies did not differ. However, in a larger series of 50 type 2 diabetic and 52 nondiabetic autototic samples, it was shown that α-cells mass was essentially the same in type 2 diabetic (366 mg) and nondiabetic subjects (342 mg), and was not influenced by sex, BMI, or type of diabetes treatment [122]. Likewise, no difference in the number of α cells between type 2 diabetic and nondiabetic cases was shown by electron microscopy evaluation of pancreatic specimens from organ donors [15]. Nevertheless, due to the concomitant reduction of β-cells, in these studies the ratio of α cells to β-cells was significantly higher in diabetic islets [34,122]. This suggests that, on the one hand

the reduction of intra-islet insulin in T2DM may contribute to a disproportionately elevated glucagon secretion [121], which could be exacerbated by defective glucose regulation of glucagon secretion (due to impaired metabolic control of the α cell ATP-regulated K$^+$ (KATP) channels [123]); on the other hand, exposure to increased intra-islet glucagon concentrations could have adverse effects on the β-cell [124].

Other features of α cells could influence the β-cell in human T2DM. In fact, subpopulations of α cells have been shown to be able to process preproglucagon by proconvertase 1/3 to produce glucagon-like peptide-1 (GLP-1) [125,126]. In addition, *ex vivo* active GLP-1 release is higher in islets from type 2 diabetic individuals [126], and recent data show the presence of dipeptidylpeptidase-4 (DPP-4, the GLP-1 inactivating enzyme) in human α cells (Figure 24.9), with reduced DPP-4 activity in type 2 diabetic islets [127]. These findings are in line with the concept that, under given circumstances human α cells could modulate their phenotype to produce GLP-1 in an attempt to protect the endangered β-cells [125–129]; this phenomenon could include α-cell production of glucose-dependent insulinotropic polypeptide, GIP [130]. This novel information is relevant to the controversial issue of the role of incretin-based therapy in T2DM [131–135].

Recent observations have pointed to yet another abnormality of T2DM islets, namely, altered endocrine cell arrangement. Especially in larger islets, architecture is sparse, and spatial cell organization appears more dispersed [10,15]. Given the importance of the above described cell-to-cell communication for normal islet cell function [105–115], this morphologic feature may have physiologic impact. Interestingly, work has shown that connexin-36 (Cx36, a key component of gap junctions) correlates with insulin gene expression in both nondiabetic and type 2 diabetic islets [136]. In addition, exposure of human islets to lipotoxic conditions reduces Cx36 expression, disrupts islet cell architecture, and decreases glucose-stimulated insulin secretion [137].

Incretin defect

Oral glucose elicits a greater insulin response than does intravenous glucose. As first demonstrated by Nauck et al. [138], when tested at matched plasma glucose concentrations (isoglycemic protocol) the oral route of glucose administration induces a robust increment in insulin secretion as compared with the intravenous route. In nondiabetic subjects, such potentiation—named incretin effect—averages 50–70% with a standard (75 g) oral glucose load, and increases with the size of the glucose load [134,139]. As depicted in Figure 24.10, the incretin effect is characteristically lost in patients with T2DM [138,140–146]. Recent work using mathematical modeling of β-cell function has made it possible to separate *glucose-mediated* from *incretin-mediated* potentiation by combined analysis of oral and intravenous isoglycemic protocols [135]. The results show that, while glucose potentiation is actually augmented
Figure 24.9 DPP-4 is present in human islet cells, co-localizing with glucagon (a), but not with insulin (b) or somatostatin (c). Source: Adapted from Omar et al. 2014 [127]. Figure 24.10 The incretin effect, measured as the difference (dark shaded areas) between the insulin secretory response to oral and intravenous (i.v.) glucose under isoglycemic conditions (top panels). Note the absence of a significant incretin effect in patients with type 2 diabetes (T2D). Source: Redrawn from data in Muscelli et al. 2008 [146]. (For a color version of this figure, please see color plate section.)

in type 2 diabetic patients compared to nondiabetic subjects (due to the hyperglycemia), incretin potentiation is severely compromised (Figure 24.11). Relevant in this regard is collated evidence documenting that the secretory response of GLP-1—the main incretin hormone—is quite variable in T2D, ranging from reduced to normal, and is poorly correlated with the extent of the incretin defect [133]. Thus, other factors, hormonal or neural, must contribute to the incretin defect of T2DM. Among the hormonal factors, glucose-dependent insulinotropic polypeptide (GIP) causes little potentiation of insulin release in T2DM despite raised GIP responses to oral stimuli [140]. Importantly, the incretin defect of T2DM, which can also be detected in youth [141] and in MODY-3 (HNF-1A) diabetes [142], is not reversed by treatment with a DPP-4 [143] or metformin [144]. These observations have led investigators to postulate that loss of incretin effect is an inherent, rather than secondary, characteristic of T2DM [145].

An important observation is that obesity *per se* is associated with an impaired incretin effect, that is, independently of glucose tolerance [146]. Because the insulin resistance of obesity involves adipose tissue as well as skeletal muscle, elevated circulating free fatty acids may be linked with the incretin defect, possibly via the reduction of Cx36 [137].

Additional aspects of β-cell dysfunction

Detailed analysis of β-cell function *in vivo* has shown that the ability of β-cells to respond to the rate of increase in plasma glucose concentration (rate sensitivity)—a response modality first identified in the isolated rat pancreas [147]—is markedly impaired in patients with T2DM [80], and is improved by bariatric surgery [87]. Furthermore, the autocrine effect of insulin to stimulate its own release has been shown to be significantly reduced in insulin-resistant states [148]. With regard to the relationship between insulin resistance and β-cell function, separate measurement of insulin sensitivity (by the euglycemic hyperinsulinemic clamp technique) and β-cell function (as resolved by mathematical modeling of C-peptide responses to oral glucose or mixed meals) has demonstrated that these two key determinants of glucose levels are numerically independent of each other across a range of glucose tolerance [25,30] but are nevertheless co-present in diabetes and prediabetes, in adults [80] as well as children [141]. Recent studies in patients undergoing pancreatoduodenectomy [149] have shed some light on this issue. In fact, insulin-resistant subjects showed an increased islet size and an elevated number of β-cells as well as α cells, resulting in an reduced β-cell-to-α-cell area, as compared to insulin-sensitive subjects. Following surgical excision of comparable portions of pancreas, the insulin response to intravenous glucose and to a mixed meal was unchanged in the insulin-sensitive individuals whereas it was markedly impaired in the insulin-resistant group.

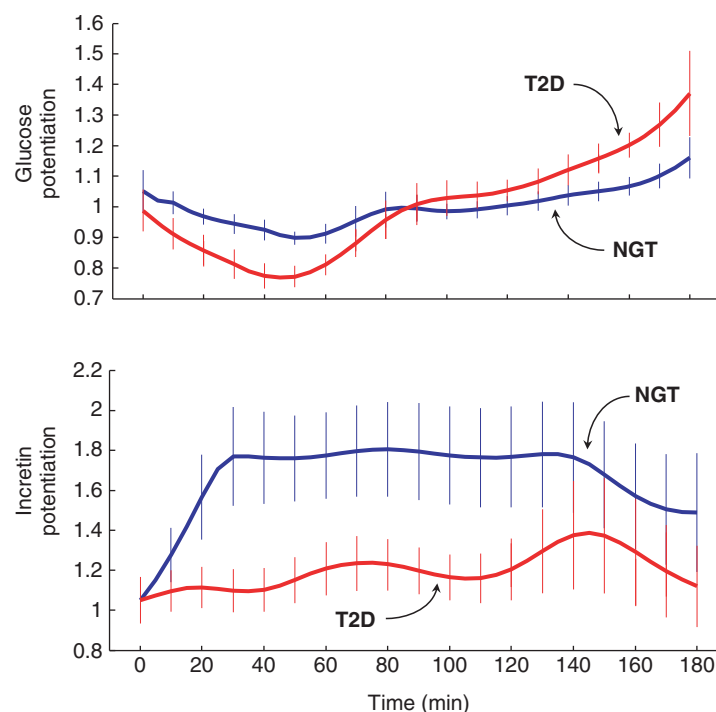
Finally, impaired β-cell glucose sensitivity is a powerful predictor of progression to dysglycemia and T2DM in subjects with normal glucose tolerance independently of insulin resistance and on top of the classical phenotypic indicators (age, adiposity, familial diabetes) [150]. In multivariate predictive


Figure 24.11 Time-course of glucose-induced and incretin-induced potentiation of insulin secretion in nondiabetic subjects (NGT) and in patients with type 2 diabetes. models, absolute insulin secretion is a positive antecedent of deteriorating glucose tolerance, thereby emphasizing the contrasting value of *absolute* insulin release viz the *dynamics* of insulin response.

Loss of β-cell functional identity

The dominance of β-cell functional impairment in T2DM implies that β-cells have lost, at least in part, their normal insulin secretory phenotype. The associated molecular features have been discussed in a number of insightful reviews and research articles, and the role of genetic, epigenetic, transcriptomic and proteomic changes has been described extensively [151–166]. At the cellular level, β-cell insulin degranulation and the recently hypothesized β-cell dedifferentiation phenomenon could play key roles. Insulin granules can be easily identified by electron microscopy on the basis of their typical morphology, characterized by a dense core and a more or less clearly visible halo [15,36,167,168]. In addition, secretory granules can be subdivided into mature and immature, based on distinct ultrastructural, biochemical, and functional characteristics [167–171], with a relative ratio of 6 to10 in normal human β-cells [18,172]. Notably, this ratio may be under genetic control, as documented by the finding that β-cells from nondiabetic carriers of the Gly(972)→Arg IRS-1 polymorphism contain a several-fold greater number of immature secretory granules and a lower number of mature granules compared to control β-cells [173]. Also, depending on the technique used, it has been estimated that the number of insulin granules in rodent β-cells ranges from 5000 to more than 10,000 per cell [168,174], of which around 10% are in close proximity to the plasma membrane ("docked" granules) [175]. A few studies have suggested that docked granules could be mainly involved in the first phase of insulin release, but this issue remains controversial [161–171,176–178].

The amount of insulin granules in β-cells from human subjects with T2DM has been investigated by electron microscopy, showing an average 30–40% reduction versus control samples, due to a lower number of mature granules [18,172]. Interestingly, the amount of docked granules has been reported to be similar in type 2 diabetic and nondiabetic β-cells, but with a much higher proportion of immature granules (around fourfold compared to the control cases) [172]. In addition to these changes, decreased gene and/or protein expression of molecules involved in vesicle exocytosis (such as syntaxin-1A, SNAP-25, VAMP-2, Munc-18, Munc 13-1, synaptotagmin V and synaptophysin) has been found in islets from type 2 diabetic patients [179]. Clearly, these changes can conceivably contribute to impair insulin turnover in β-cells from diabetic subjects [180]. At the same time, the insulin granule density of human type 2 diabetic β-cells can be restored (Figure 24.12). In fact, when islets prepared from type 2 diabetic donors were studied after a 24-hour incubation in culture medium containing 5.5 mM glucose and therapeutical concentration of metformin, the volume of mature insulin granules increased from 1.9 ± 0.5 to $3.4 \pm 0.3\%$, which was similar to the value in nondiabetic β-cells ($3.2 \pm 0.7\%$) [18]. Although further work is needed, these latter results are in agreement with observations showing replenishment of β-cell granules after reduction of blood glucose in the diabetic *Psammomys obesus* [181], and with *ex vivo* and *in vivo* experiments demonstrating recovery of insulin secretory function of human type 2 diabetic β-cells [26,88,165,182–184].

Degranulation can also lead to underestimation of β-cell number. In a recent article [15], pancreas samples from nondiabetic and matched type 2 diabetic subjects were studied in parallel by immunocytochemistry and electron microscopy. In addition, morphologic, ultrastructural and glucose-stimulated insulin secretion experiments were performed with nondiabetic islets after 24 hours in culture in the presence of 22.2 mM glucose [15]. By immunocytochemistry, the fractional islet

Untreated type 2 diabetic β-cell

Type 2 diabetic β-cell cultured at normal glucose level and therapeutic concentration of metformin
Figure 24.12 Electron microscopy micrographs showing insulin granules in a type 2 diabetic β-cell before (left panel) and after (right panel) culture in a medium containing 5.5 mM glucose and therapeutical concentration of metformin, showing granule replenishment. Source: Adapted from Marchetti 2004 [18].
Figure 24.13 Schematic representation of the dedifferentiation concept, according to Wajchenberg 2007 [184]. Under normal conditions, β-cells have cytoplasmic FOXO1 (yellow); during metabolic stress, insulin production is maintained (green), with FOXO1 translocating to the nucleus (red) to promote β-cell health. With persisting hyperglycemia, FOXO1 expression declines (blue nucleus), other transcription factors are reactivated and insulin production decreases (gray). At this stage, former β-cells may revert to an uncommitted endocrine progenitor stage (gray) or undergo conversion to cells producing other hormones (orange). (For a color version of this figure, please see color plate section.)

insulin-positive area was 30–40% lower in type 2 diabetic islets, as expected. However, electron microscopy showed that the amount of β-cells in the diabetic islets was only marginally decreased, but marked β-cell degranulation was evident. These findings were reproduced after exposing nondiabetic islets to high glucose. It is therefore possible that a proportion of β-cells in T2DM islets may not be detectable by standard immunohistochemistry staining due to insulin degranulation, potentially leading to an overestimation of β-cell loss. At the same time, the study confirmed reduced glucose-stimulated insulin secretion from both type 2 diabetic islets and nondiabetic islets exposed to high glucose, indicating that major β-cell secretory impairment may indeed occur without any actual loss of β-cells [15].

Interestingly, some islet cells expressing insulin may also show glucagon immunoreactivity [12,149]. In a study, it has been reported that the percentage of insulin-positive cells that were also glucagon immunoreactive is greater in human T2DM ($3.2 \pm 1.4\%$) than in nondiabetic samples ($0.4 \pm 0.1\%$), and that this proportion may be much higher ($16.8 \pm 5.0\%$) depending on the type of antidiabetic therapy [12]. The presence of cells expressing both insulin and glucagon has been also confirmed by gene expression studies on "β-cells" obtained by the laser capture microdissection technique [161], and could be interpreted as a potential β-cell transdifferentiation to α cells in response to insulin resistance [149]. The secretory phenotype of these dual hormone-positive cells is currently unknown. However, cells containing both insulin and glucagon may also be considered as β-cells at some stage of differentiation. In rodent experiments deleting the key transcription factor FOXO1 in combination with permanent genetic labeling of β-cells, it has been shown that the apparent loss of β-cells was not due to their

death, but to the missed expression of fundamental β-cell genes, including insulin, glucose transporter 2, and glucokinase [185]. Furthermore, a proportion of FOXO1-deficient β-cells became able to express glucagon [185], all this suggesting that under given conditions insulin degranulation could be a step towards more profound β-cell changes, such as dedifferentiation and transdifferentiation [186–188] (see Figure 24.13). Although some evidence is available to suggest that β-cells dedifferentiation may also occur in human T2DM [188,189], clearly more work is needed to evaluate if and to what extent dedifferentiation has a role in the loss of β-cell functional identity in the disease. If this was the case, new possibilities could be envisaged to protect and/or rescue the β-cell. For instance, resveratrol administration prevented β-cell dedifferentiation in the *Rhesus monkey* on a diabetogenic diet [190], and insulin therapy with restoration of near-normal glycemia was associated with β-cell redifferentiation in a mouse model of insulin-secretory deficiency by β-cell inexcitability [191].

Conclusions

β-cell failure is central to the onset and progression of human T2DM. Both decreased β-cell mass and impaired insulin secretory function have been documented *ex vivo* and *in vivo*, due to inherited and acquired factors, leading to varying combinations of molecular and cellular alterations typical of the disease. Growing evidence indicates that functional defects are likely to play the dominant role in most cases of diabetes, with a proportion of β-cells escaping death at the expense of the acquisition of a nonfunctional phenotype. Protection and rescue of the β-cell insulin secretory function should represent the primary objective of any intervention aimed at the prevention and treatment of T2DM.

CHAPTER 25

Pathogenesis of type 2 diabetes mellitus

Ralph A. DeFronzo

Diabetes Division, University of Texas Health Science Center, San Antonio, TX, USA

Key points

- Type 2 diabetes is characterized by multiple pathophysiologic disturbances including:
  - muscle insulin resistance → decreased/glucose uptake
  - hepatic insulin resistance → increased/glucose production
  - adipocyte insulin resistance → increase plasma FFA and increased insulin resistance provoking adipocytokines
  - progressive β-cell failure
  - hyperglucagonemia and increased hepatic sensitivity to glucagon
  - impaired incretin (GLP-1 and GIP) effect
  - increased renal glucose reabsorption
  - brain neurotransmitter dysfunction leading to impaired appetite suppression and weight gain.
- Insulin resistance is the earliest detectable abnormality in the natural history of type 2 diabetes.
- With progressive β-cell failure, in the presence of insulin resistance, individuals progress from normal glucose tolerance to impaired glucose tolerance to overt type 2 diabetes.

Normal glucose homeostasis

Any discussion of the pathogenesis of type 2 diabetes mellitus (T2DM) must start with a review of mechanisms involved in the maintenance of normal glucose homeostasis in the basal or postabsorptive state (10–12-h overnight fast) and following ingestion of a typical mixed meal [1–4]. In the postabsorptive state the great majority of total body glucose disposal takes place in insulin independent tissues. Thus, ~50% of all glucose utilization occurs in the brain, which is insulin independent and becomes saturated at a plasma glucose concentration of about 40 mg dL^{-1} [4,5]. Another 25% of glucose disposal occurs in the splanchnic area (liver plus gastrointestinal tissues) and is also insulin independent. The remaining 25% of glucose utilization in the postabsorptive state takes place in insulin-dependent tissues, primarily muscle, and to a lesser extent adipose tissue. Basal glucose utilization, ~2.0 mg kg^{-1} min^{-1}, is precisely

matched by the rate of endogenous glucose production (Figure 25.1). Approximately 85% of endogenous glucose production is derived from the liver, and the remaining 15% is produced by the kidney. Glycogenolysis and gluconeogenesis contribute equally to the basal rate of hepatic glucose production.

Following glucose ingestion, the increase in plasma glucose concentration stimulates insulin release, and the combination of hyperinsulinemia and hyperglycemia (i) stimulates glucose uptake by splanchnic (liver and gut) and peripheral (primarily muscle) tissues (Table 25.1), and (ii) suppresses endogenous (primarily hepatic) glucose production [1–4,6–10]. The majority (~80–85%) of glucose uptake by peripheral tissues occurs in muscle, with a small amount (~4–5%) being metabolized by adipocytes. Although fat tissue is responsible for only a small amount of total body glucose disposal, it plays a very important role in the maintenance of total body glucose homeostasis by regulating the release of free fatty acids (FFA) from stored triglycerides (see later) and through the production of adipocytokines that influence insulin sensitivity in muscle and liver [11–13]. Insulin is a potent antilipolytic hormone and even small increments in the plasma insulin concentration markedly inhibit lipolysis, leading to a decline in the plasma FFA level [12]. The decline in plasma FFA concentration augments muscle glucose uptake and contributes to the inhibition of hepatic glucose production. Thus, changes in the plasma FFA concentration in response to increased plasma levels of insulin and glucose play an important role in the maintenance of normal glucose homeostasis [11–13].

Glucagon also plays a central role in the regulation of glucose homeostasis [14,15]. Under postabsorptive conditions approximately half of total hepatic glucose output is dependent upon the maintenance of normal basal glucagon levels and inhibition of basal glucagon secretion with somatostatin causes a reduction in hepatic glucose production and plasma glucose concentration. After a glucose-containing meal, glucagon secretion is inhibited by hyperinsulinemia, and the resultant

hypoglucagonemia contributes to the suppression of hepatic glucose production and maintenance of normal postprandial glucose tolerance.

The route of glucose entry into the body also plays an important role in the distribution of administered glucose and overall glucose homeostasis [14,16,17]. Intravenous (i.v.) insulin exerts only a small stimulatory effect on splanchnic (liver plus gut) glucose uptake, while i.v. glucose augments splanchnic glucose uptake in direct proportion to the increase in plasma glucose concentration [6]. In contrast, oral glucose administration markedly enhances splanchnic glucose uptake. The portal signal that stimulates hepatic glucose uptake after glucose ingestion is directly proportional to the negative hepatic artery-portal vein glucose concentration gradient [9]. As this gradient widens, the splanchnic nerves are stimulated and this activates a neural reflex, in which vagal activity is enhanced and sympathetic nerves innervating the liver are inhibited. These neural changes augment liver glucose uptake and stimulate hepatic glycogen synthase, while simultaneously inhibiting glycogen phosphorylase. In contrast to i.v. glucose/insulin administration, where muscle accounts for the majority (∼80–85%) of glucose disposal, the splanchnic tissues are responsible for the removal of ∼30–40% of an ingested glucose load.

Glucose administration via the gastrointestinal tract also has a potentiating effect on insulin secretion. Thus, the plasma insulin response following oral glucose is about twice as great as that following i.v. glucose despite equivalent increases in the plasma glucose concentration. This incretin effect is related to the release of glucagon-like peptide-1 (GLP-1) from the L cells in the large intestine and glucose-dependent insulinotropic polypeptide (previously called gastric inhibitory polypeptide) (GIP) from the K cells in the early part of the small intestine [18–20]. GLP-1 also inhibits glucagon secretion and the decline in plasma glucagon concentration contributes to suppression of hepatic glucose production following meal ingestion. GLP-1 and GIP are released in response to nutrient absorption by the L and K cells [18–20], and in response to a meal increased circulating levels of GLP-1 and GIP can be detected within minutes, before nutrients can reach the K cells in the duodenum and long before they reach the L cells in the distal small intestine and early large intestine. This early release of GLP-1 and GIP is mediated via neural impulses that are carried to centers in the hypothalamus and back to the intestinal cells via the vagus nerve [21]. GLP-1 and GIP have their own receptors on the β cell and augment insulin secretion by activation of adenyl cyclase [18–20]. Importantly, the stimulation of insulin secretion by GLP1 and GIP is glucose-dependent, that is, insulin release is augmented in the presence of hyperglycemia and the stimulatory effect of both GLP-1 and GIP wanes as the blood glucose concentration returns to normoglycemic levels.

Natural history of type 2 diabetes

The natural history of T2DM has been well described in multiple populations [1,3,22–32] and is reviewed in references [1] and [3]. Individuals destined to develop T2DM inherit a set of genes from their parents that make their tissues resistant to insulin [1–3,33–37] and the insulin resistance is aggravated by weight gain and physical inactivity. Hepatic insulin resistance is manifested by an overproduction of glucose during the basal state despite the presence of fasting hyperinsulinemia [38] and an impaired suppression of hepatic glucose production (HGP) in response to insulin [39], as occurs following a meal [40]. Muscle insulin resistance [6,36,39,41] is manifest by impaired glucose uptake following ingestion of a carbohydrate meal and results in postprandial hyperglycemia [40]. The origin of the insulin resistance can be traced to the genetic background [2,34,42]. However, the epidemic of diabetes that has enveloped Westernized countries primarily results from the epidemic of obesity and physical inactivity [43]. Both obesity [44] and decreased physical activity [45] are insulin-resistant states and, when added to the genetic burden of the insulin resistance, place a major stress on the pancreatic β cells to augment their secretion of insulin to offset the defect in insulin action [1–3]. Initially the β cells augment their secretion of insulin to offset the insulin resistance and glucose tolerance remains normal [46]. However, with time the β cells begin to fail and initially the postprandial plasma glucose levels and subsequently the

fasting plasma glucose concentration rise, leading to the onset of overt diabetes [1–3,47,48]. Collectively, the insulin resistance in muscle and liver and β-cell failure have been referred to as the Triumvirate [1] (Figure 25.1). The resultant hyperglycemia and poor metabolic control may cause a further decline in insulin sensitivity, but it is the progressive β-cell failure that determines the rate of disease progression.

Although the relative contributions of insulin resistance and β-cell failure to the development of T2DM may vary amongst different ethnic groups [49], progressive β-cell failure superimposed upon a background of insulin resistance represent the core pathophysiologic defects responsible for the development of overt diabetes [1–3,50].

The natural history of T2DM described above [1–3] is depicted by a prospective 6-year study carried out by Felber and colleagues [26] (Figure 25.2). Subjects had a euglycemic insulin clamp to measure tissue sensitivity to insulin and an oral glucose tolerance test (OGTT) to provide a measure of glucose tolerance and β-cell function. As lean subjects gain weight, insulin sensitivity declines but glucose tolerance remains normal because of the compensatory increase in insulin secretion. With time the obese normal glucose-tolerant (NGT) individuals progress to impaired glucose tolerance (IGT) in association with a further reduction in insulin sensitivity. However, the rise in plasma glucose concentration is modest because of a further compensatory increase in insulin secretion. However, people with IGT are in a very precarious position, since they are maximally or near maximally insulin resistant, and their β-cell function is severely impaired even though, in absolute terms, their plasma insulin response is increased (see subsequent

discussion). With time the β cells cannot continue to produce these very large amounts of insulin and the obese IGT individual progresses to overt diabetes. The decline in glucose tolerance is associated with a marked decrease in insulin secretion without further or minimal change in insulin sensitivity (Figure 25.2). This characteristic rise in insulin response to insulin resistance and hyperglycemia, followed by a subsequent decline, has been referred to as Starling's curve of the pancreas [1] and is characteristic of the natural history of T2DM in many diverse ethnic populations [1–3,22–32,51,52].

A similar pattern of insulin secretion has been observed during the development of diabetes in primates [53,54]. The aging primate becomes obese and a high percentage develop typical T2DM. The earliest detectable abnormality (preceding the onset of diabetes mellitus) is a decrease in tissue sensitivity to insulin with a compensatory increase in fasting and glucose-stimulated plasma insulin concentrations. With time, the high rate of insulin secretion cannot be maintained, the β cell starts on the downward slope of Starling's curve and fasting hyperglycemia and glucose intolerance ensue.

β-Cell function

Although the plasma insulin response to the development of insulin resistance typically is increased during the natural history of T2DM (Figure 25.2), this does not mean that the β cell is functioning normally. To the contrary, studies have demonstrated that the onset of β-cell failure occurs much earlier and is more severe than previously appreciated. In the San Antonio Metabolism (SAM) study and the Veterans Administration Genetic Epidemiology Study (VAGES), a large number of subjects with NGT ($n = 318$), IGT ($n = 259$), and T2DM ($n = 201$) were studied [55–58]. All subjects had an OGTT with plasma glucose and insulin concentrations measured every 15 min to evaluate overall glucose tolerance and β-cell function and a euglycemic insulin clamp to measure insulin sensitivity. Simply measuring the plasma insulin response to a glucose challenge does not provide a valid index of β-cell function [59]. The β cell responds to an *increment* in glucose (ΔG) with an *increment* in insulin (ΔI) [59]. Thus, a better measure of β-cell function is ΔI/ΔG. However, the β cell also recognizes the severity of insulin resistance and adjusts its secretion of insulin to offset the defect in insulin action [46,59–61]. Thus, the gold standard for measuring β-cell function is the insulin secretion/insulin resistance (ΔI/ΔG ÷ IR), or so-called disposition, index. Although subjects with IGT have an increase in the absolute plasma insulin concentration, this should not be interpreted to mean that the β cells in these individuals are functioning normally.

Figure 25.3 depicts the insulin secretion/insulin resistance index (ΔI/ΔG ÷ IR) in NGT, IGT, and T2DM subjects as a function of the 2-h plasma glucose concentration during the OGTT. Subjects in the upper tertile of "normal" glucose
Figure 25.2 Summary of the plasma insulin (top) (dashed line, open circles) and plasma glucose (bottom) responses during a 100-g OGTT and tissue sensitivity to insulin intolerant (OB-GLU INTOL), obese hyperinsulinemic diabetic (OB-DIAB Hi INS), and obese hypoinsulinemic diabetic subjects (OB-DIAB Lo INS). See text for a detailed discussion. Source: DeFronzo RA. *Diabetes* 1988;**37**:667–687.
Figure 25.3 Insulin secretion/insulin resistance (disposition) index (defined as increment in insulin/increment in glucose + insulin resistance [ΔINS/ΔGLU ÷ IR]) in individuals with normal glucose tolerance (NGT), impaired glucose tolerance (IGT) and type 2 diabetes mellitus (T2DM) as a function of the 2-h plasma glucose (PG) concentration in lean (closed cirlces) and obese (open cirlces) subjects. Source: DeFronzo RA. *Diabetes* 2009;**58**:773–795.

tolerance (2-h PG = 120–139 mg dL^{-1}) have lost two thirds of their β-cell function (see first arrow in Figure 25.3), while subjects in the upper tertile of IGT (2-h PG = 180–199 mg dL^{-1}) have lost 80–85% of their β-cell function (see second arrow in Figure 25.3). Similar results have been presented in other publications [22,23,25,31,62]. In biomedical phenomena, most reactions take place as a log function. Figure 25.3 depicts the natural log of the 2-h plasma glucose concentration during the OGTT as a function of the natural log of the insulin secretion/insulin resistance (β-cell function) index. These two variables are strongly and linearly related ($r = 0.91$, $p < 0.00001$). There are no cut points that distinguish NGT from IGT or IGT from T2DM. Rather, glucose intolerance is a continuum, and subjects simply move up and down this curve as a function of the insulin secretion/insulin resistance index. Therefore, the current diagnostic criteria [63] for IGT and T2DM are quite arbitrary and glucose tolerance should be viewed as a continuum of risk. The higher the 2-h plasma glucose concentration, even within the range of IGT, the greater is the risk for microvascular complications.

The previous discussion has focused on β-cell function and clearly demonstrates that β-cell health is severely impaired well before the onset of T2DM and even before the development of IGT. Even more ominous are studies demonstrating a significant reduction in β-cell mass in prediabetic (IFG/IGT) individuals [64–66]. In a postmortem analysis, these investigators demonstrated that as individuals progress from NGT to impaired fasting glucose (IFG), there was a 50% decline in β-cell volume, suggesting a significant loss of β-cell mass long before the onset of T2DM. With the progression to overt diabetes, there was a further loss of β-cell volume. Although β-cell volume should not be equated with β-cell mass, these results indicate that significant loss of β-cell mass occurs long before the onset of T2DM, according to current diagnostic criteria [63]. Multiple

other studies have also demonstrated a significant loss of β-cell mass before the onset of diabetes with a further decrease in β-cell mass with progression to overt diabetes [64–68].

In summary, at the upper tertile of IGT [55–58,62], individuals have lost over 80% of their β-cell function, while the results of autopsy studies [64–66] indicate that subjects with "prediabetes" have experienced a signifiant loss of β-cell mass. In humans this presents a major problem since no therapeutic intervention has been shown to increase β-cell number.

Type 2 diabetes with hypoinsulinemia

A large body of clinical and experimental evidence documents that hyperinsulinemia and insulin resistance precede the onset of T2DM. Nonetheless, a number of studies have shown that absolute insulin deficiency, with or without impaired tissue insulin sensitivity, can lead to the development of T2DM. This scenario is best exemplified by patients with maturity onset diabetes of youth (MODY) [69–71]. This familial subtype of T2DM is characterized by early age of onset, autosomal dominant inheritance with high penetrance, mild-to-moderate fasting hyperglycemia, and impaired insulin secretion.

MODY originally was described by Fajans and subsequently it was demonstrated that MODY-1 resulted from a nonsense mutation in exon 7 of the hepatic nuclear factor (HNF4α) gene [72]. It later was demonstrated that MODY in French families resulted from mutations in the glucokinase gene on chromosome 7p (MODY-2) [73]. More than eight specific mutations in different genes have been implicated in the MODY profile including glucokinase and seven transcription factors [69–74]: MODY-1 = HNF4α; MODY-2 = glucokinase; MODY-3 = HNF1α; MODY-4 = insulin promoter factor 1; MODY-5 = HNF1β; MODY-6 = neurogenic differentiation 1/β-cell E-box transactivator 2; MODY-7 = KLF11 or Kruppel-like factor 11 that regulates Pdx1 transcription in β cells; MODY-8 = carboxyl-ester lipase gene. HNF1α, HNF1β, and HNF4α constitute part of a network of transcription factors that function collectively during embryonic development and during adulthood to regulate the expression of the insulin gene. The hallmark defect in MODY individuals is impaired insulin secretion in response to glucose and other secretagogues. However, peripheral tissue resistance to insulin and abnormalities in hepatic glucose metabolism have also been shown to play some role in the development of impaired glucose homeostasis [75]. Although glucokinase mutations are characteristic of MODY-2, genetic studies in typical older-onset type 2 diabetic individuals have shown that glucokinase mutations account for less than 1% of the common form of T2DM [76].

Cerasi, Luft, Hales, and coworkers [77–79] have championed the view that insulin deficiency represents the primary defect responsible for glucose intolerance in typical type 2 diabetic individuals who do not have glucokinase or other MODY mutations. According to these investigators, impaired early

insulin secretion leads to an excessive rise in plasma glucose concentration and the resultant hyperglycemia is responsible for late hyperinsulinemia. Hales and colleagues [78] have demonstrated that many lean Caucasians with mild fasting hyperglycemia ($<140 \text{ mg dL}^{-1}$, 7.8 mmol L^{-1}) are characterized by insulin deficiency at all time points during an OGTT. An impaired early insulin response has also been a characteristic finding in Japanese Americans who progress to T2DM [79]. Unfortunately, none of these studies provided information about insulin sensitivity. In Caucasians several groups [80,81] have demonstrated normal insulin sensitivity in a minority of type 2 diabetic individuals and it has been suggested that up to 50% of African American type 2 diabetic patients who reside in New York City are characterized by severely impaired insulin secretion and normal insulin sensitivity [82]. A similar defect in insulin secretion has been described in black African type 2 diabetic individuals living in Cameroon [83].

In summary, it is clear that impaired insulin secretion—in the absence of insulin resistance—can lead to the development of full-blown T2DM. However, it remains to be clarified how frequently a pure β-cell defect results in typical T2DM in the general population.

First-phase insulin secretion

In response to i.v. glucose, insulin is secreted in a biphasic pattern with an early burst of insulin release within the first 10 min followed by a progressively increasing phase of insulin secretion that persists as long as the hyperglycemic stimulus is present [84]. This biphasic insulin response is not observed after oral glucose, because of the more gradual rise in plasma glucose concentration. Loss of first-phase insulin secretion is a characteristic and early abnormality in patients destined to develop T2DM [1–3]. In most type 2 diabetic subjects a reduction in the early phase of insulin secretion during the OGTT (0–30 min) and during the IVGTT (0–10 min) becomes evident when fasting plasma glucose concentration exceeds $>110–120 \text{ mg dL}^{-1}$ ($6.1–6.7 \text{ mmol L}^{-1}$) [1–3,48,85,86]. During the OGTT, the defect in early insulin secretion is most obvious if the incremental plasma insulin response at 30 min is expressed relative to the incremental plasma glucose response at 30 min ($\Delta I_{30}/\Delta G_{30}$). Although the first-phase insulin secretory response to i.v. glucose characteristically is diminished or lost in T2DM, this defect is not consistently observed until the fasting plasma glucose concentration rises to $\sim115–120 \text{ mg dL}^{-1}$ ($6.4–6.7 \text{ mmol L}^{-1}$). The defect in first-phase insulin response can be partially restored with tight metabolic control [87–91], indicating that at least part of the defect is acquired (see subsequent discussion). Loss of the first phase of insulin secretion has important pathogenic consequences, since this early burst of insulin primes insulin target tissues, especially the liver, that are responsible for the maintenance of normal glucose homeostasis [60,61].
Figure 25.4 Pathogenetic factors implicated in the progressive impairment in insulin secretion in T2DM.

Pathogenesis of β-cell failure (Figure 25.4)

Age. Numerous studies [92,93] have demonstrated a progressive age-related decline in β-cell function. This is consistent with the well-established observation that the incidence of diabetes increases progressively with advancing age. However, it is clear that factors in addition to age must be involved to account for the major impairment in β-cell function in T2DM.

Genes. β-Cell failure also clusters in families, and studies in first-degree relatives of T2DM parents and in twins have provided strong evidence for the genetic basis of the β-cell dysfunction [94–96]. A number of genes have been associated with T2DM in multiple ethnic populations. Of these, the most common are transcription factors associated with β-cell function [34,97–102]. In Finnish families with T2DM impaired insulin secretion is an inherited trait with evidence for a susceptibility locus on chromosome 12 [103]. Of these genes, the transcription factor TCF7L2 is best established [97,98]. Studies by Groop and colleagues [104] have shown that the T-allele of single nucleotide polymorphism rs7903146 of the TCF7L2 gene is associated with impaired insulin secretion *in vivo* and reduced responsiveness to glucagon-like peptide 1 (GLP-1). Both the CT and TT genotypes predict T2DM in multiple ethnic groups [105]. In both the Malmö and Botnia studies, presence of either the CT or TT genotype was associated with a significant reduction in the diabetes-free survival time [104]. TCF7L2 encodes for a transcription factor involved in Wnt signaling, which plays a central role in the regulation of β-cell proliferation and insulin secretion [106]. A number of other transcription factors have also been associated with impaired insulin secretion in T2DM including: GCK, a gene responsible for MODY-2; SLC30A8, a zinc transporter involved in maintaining the appropriate amount of zinc in β-cell secretion granules; KCNJ11 and ABCC8 which encode the subunits of the ATP-sensitive potassium channel; and others [102].

At present there are no known therapeutic interventions that can reverse either the age-related decline or genetic-related factors responsible for impaired insulin secretion. However, there

are a number of causes of β-cell failure that can be reversed or ameliorated.

Insulin resistance. Insulin resistance places an increased demand on the β cells to hypersecrete insulin [46] and thus contributes to the progressive β-cell failure in T2DM [107]. Therefore, interventions aimed at enhancing insulin sensitivity are of paramount importance. The precise mechanism(s) via which insulin resistance leads to β-cell failure remain(s) unknown. It is commonly stated that the β cell, by being forced to continuously hypersecrete insulin, eventually wears out. Although simplistic in nature, this explanation lacks a mechanistic cause. Nonetheless, β cell "unloading" with thiazolidinediones in IGT subjects has been shown to markedly enhance β-cell function and reduce the conversion to T2DM [107,108]. An alternate hypothesis, for which considerable evidence exists, is that the etiology of the insulin resistance also is responsible for the β-cell failure. Thus, excess deposition of fat (long chain-fatty acyl CoAs, diacylglycerol, and ceramide) in liver and muscle impairs insulin signaling, causing insulin resistance in these organs, that is, lipotoxicity. Similarly, deposition of fat in the β cell and chronically elevated plasma FFA lead to impaired insulin secretion and β-cell failure [109–112]. Hypersecretion of islet amyloid polypeptide (IAPP) has also been implicated as a cause of the β-cell failure [54,113,114]. IAPP is especially toxic to the β cell in the presence of elevated intracellular fat content [114]. Further, as the IAPP ammulates it coalesces and encroaches upon the β cell, leading to β cell destruction [54,67,114,115]. Lastly, studies in the β-cell insulin receptor knock out (BIRKO) mouse [116] and in humans with gly → arg substitution of codon 972 of IRS-1 [117–119] have demonstrated that defects in insulin signaling in the β cell are associated with impaired insulin secretion.

Lipotoxicity. Lipid deposition in the β cell [109,111,112] and chronic elevation of the plasma FFA concentration impair insulin secretion, and this has been referred to as lipotoxicity. A physiologic elevation of the plasma FFA concentration for as little as 48 hours markedly impairs insulin secretion in genetically predisposed individuals [110] (Figure 25.5). *In vivo* studies in rodents [120,121] and *in vitro* studies [122,123] also support an important role for lipotoxicity. Incubation of human pancreatic islets for 48 h with FFA (oleate-to-palmitate ratio 2:1) impairs both the acute and late insulin response, inhibits insulin mRNA expression, and reduces islet insulin content [123]. The peroxisome proliferator–activated receptor (PPAR)γ agonist, rosiglitazone, has been shown to prevent all of these deleterious effects of FFA [123,124]. Consistent with these *in vitro* observations, both rosiglitazone and pioglitazone markedly improve the insulin secretion/insulin resistance index *in vivo* in type 2 diabetic humans [125]. Weight loss, which mobilizes fat out of the β cell, also reverses lipotoxicity and preserves β-cell function [109].

Glucotoxicity. Chronically elevated plasma glucose levels impair β-cell function, and this has been referred to as glucotoxicity [126]. Studies by Rossetti et al. [127] have provided definitive proof of this concept. Partially pancreatectomized diabetic rats are characterized by severe defects in both first- and second-phase insulin secretion compared with control rats. Phlorizin, an inhibitor of renal glucose transport, normalizes the plasma glucose profile without change in any other circulating metabolites and restores both the first and second phases of insulin secretion. *In vitro* studies with isolated human islets have also demonstrated that chronic exposure to elevated plasma glucose levels impairs insulin secretion [128,129]. In rats, elevation of the mean day-long plasma glucose concentration *in vivo* by as little as 16 mg dL^{-1} leads to a marked inhibition of glucose-stimulated insulin secretion in the isolated perfused pancreas [130]. In humans correction of hyperglycemia with insulin [87,89–91,131,132] or inhibitors of renal glucose tranpsort (DeFronzo, unpublished results) reverses the glucotoxic effect of chronic hyperglycemia on the β cells [80–84], leading to improved first- and second-phase insulin secretion, as well as reversal of hepatic and muscle insulin resistance.

IAPP. Excessive secretion of IAPP with subsequent amyloid deposition within the pancreas has also been shown to contribute to progressive β-cell failure in T2DM [54,113,114,133]. Convincing evidence for a pathogenic role of IAPP exists in rodents [134,135] and baboons [54,67,115] and the natural history of pancreatic amylin deposition in humans parallels that in rodents and primates [136].
Figure 25.5 Effect of physiologic elevation (48 h) in the plasma FFA concentration (brought about by lipid infusion) on plasma C-peptide concentration (left) and insulin secretory response (deconvolution of the plasma C-peptide curve) (right) in offspring of two type 2 diabetic parents. Source: DeFronzo RA. *Diabetes* 2003;**52**:2461–2474.

The baboon genome shares more than 98% homology with the human genome [137,138]. Therefore, results in baboons are likely to be pertinent to those in humans. As the relative amyloid area of the pancreatic islets increase from <5.5% to >51%, there is a progressive decline in the log of HOMA-β, which was strongly correlated with the increase in fasting plasma glucose concentration [54]. Studies by the investigators [139,140] have provided additional evidence for a β-cell toxic effect for soluble IAPP fibrils.

It follows that interventions that improve insulin sensitivity, that is, TZDs/metformin/weight loss, by leading to a reduction in insulin secretion, and therefore IAPP secretion (insulin and IAPP are co-secreted in a one-to-one molar ratio), would be expected to preserve β-cell function, and rosiglitazone has been shown to protect human islets against IAPP toxicity by a PI-3 kinase-dependent pathway [141].

Incretins. In T2DM some investigators have demonstated a small decline in GLP-1 secretion or a delayed GLP-1 response (reviewed in [142]), while GIP secretion has been reported to be normal or slightly increased [142]. More importantly, there is severe resistance to the stimulatory effect of both GLP-1 and GIP [143–145]. The resistance to GLP-1 can be observed in individuals with IGT and worsens progressively with progression to T2DM [146]. Of note the resistance to GLP-1 can be overcome by infusing GLP-1 [147] or administration of GLP-1 analogues [148–150] to generate pharmacologic levels (70–90 pM) of the incretin. Tight glycemic control for as little as 4 weeks can improve the β cells' insulin secretory response to both GLP-1 and GIP [151]. Studies in patients with chronic pancreatitis and T2DM also indicate that the reduced incretin defect in T2DM is not a primary effect for the development of impaired insulin secretion [152]. Thus, β-cell resistance to GLP-1 and GIP is another manifestation of glucotoxicity.

In utero fetal malnutrition

Low birth weight is associated with the development of IGT and T2DM in a number of populations [153,154]. Developmental studies in animals and humans have demonstrated that poor nutrition and impaired fetal growth (small babies at birth) are associated with impaired insulin secretion and/or reduced β-cell mass. Fetal malnutrition can also lead to the development of insulin resistance later in life [155]. One could hypothesize that an environmental influence, for example, impaired fetal nutrition leading to an acquired defect in insulin secretion or reduced β-cell mass, when superimposed on insulin resistance, could eventuate in T2DM later in life. Thus, during the normal aging process, with the onset of obesity, or with a worsening of the genetic component of the insulin resistance, the β cell would be called upon to augment its secretion of insulin to offset the defect in insulin action. If β-cell mass (or function) is reduced (or impaired) by an environmental insult during fetal life, this would lead to the development of IGT and eventually overt T2DM. Although such a defect would limit the maximum amount of insulin that could be secreted, it would not explain the progressive decline in insulin secretion in response to physiologic stimuli as individuals progress from NGT to IGT to overt T2DM mellitus.

Summary. Although insulin resistance in liver and muscle are well established early in the natural history of the disease, overt T2DM does not occur in the absence of progressive β-cell failure.

Insulin resistance and type 2 diabetes mellitus

In cross-sectional studies and long-term, prospective longitudinal studies hyperinsulinemia has been shown to precede the onset of T2DM in all ethnic populations with a high incidence of T2DM [1–3,156–164]. Studies utilizing the euglycemic insulin clamp, minimal model, and insulin suppression techniques have provided direct quantitative evidence that the progression from normal to impaired glucose tolerance is associated with the development of severe insulin resistance, whereas plasma insulin concentrations, both in the fasting state and in response to a glucose load (Figures 25.3 and 25.4) are increased when viewed in absolute terms (see earlier discussion about insulin secretion).

Himsworth and Kerr, using a combined oral glucose and i.v. insulin tolerance test, were the first to demonstrate that tissue sensitivity to insulin was diminished in type 2 diabetic patients [165]. In 1975 Reaven and colleagues, using the insulin suppression test, provided further evidence that the ability of insulin to promote tissue glucose uptake in T2DM was severely reduced [166]. A defect in insulin action in T2DM also has been demonstrated with the arterial infusion of insulin into the brachial artery (forearm muscle) and femoral artery (leg muscle), as well as with radioisotope turnover studies, the frequently sampled i.v. glucose tolerance test, and the minimal model technique [1–3,6,167–169].

DeFronzo et al., using the more physiologic euglycemic insulin clamp technique, have provided the most conclusive documentation that insulin resistance is a characteristic feature of lean, as well as obese, type 2 diabetic individuals [1–3,6,12,170,171]. Because diabetic patients with severe fasting hyperglycemia (>180–200 mg dL^{-1}, 10.0–11.1 mmol L^{-1}) are insulinopenic (Figure 25.3), and because insulin deficiency is associated with the emergence of a number of intracellular defects in insulin action, these initial studies focused on diabetics with mild to modest elevations in the fasting plasma glucose concentration (mean = 150 ± 8 mg dL^{-1}, 8.3 ± 0.4 mmol L^{-1}). Insulin-mediated whole-body glucose disposal in these lean diabetics was reduced by ∼40–50%, providing conclusive proof of the presence of moderate to severe insulin resistance. Three additional points are noteworthy: (i) lean type 2 diabetics with more severe fasting hyperglycemia (198 ±10 mg dL^{-1}) have a severity of insulin resistance that is only slightly (10–20%)
Figure 25.6 Dose-response curve relating the plasma insulin concentration to the rate of insulin-mediated whole-body glucose uptake in control (solid circles, solid line) and type 2 diabetic (open circles, dashed line) subjects. *$p < 0.01$ vs. control subjects. Figure 25.7 Summary of HGP in 77 normal-weight type 2 diabetic subjects (open circles) with fasting plasma glucose concentrations ranging from 105 to >300 mg dL^{-1}; 72 control subjects matched for age and weight are shown by solid circles. In the 33 diabetic subjects with fasting plasma glucose levels <140 mg dL^{-1} (shaded area), the mean rate of HGP was identical to that of control subjects. In diabetic subjects with fasting plasma glucose concentrations >140 mg dL^{-1}, there was a progressive rise in HGP that correlated closely ($r = 0.847$, $p < 0.001$) with the fasting plasma glucose concentration. greater than in diabetics with mild fasting hyperglycemia; (ii) the defect in insulin action is observed at all plasma insulin concentrations, spanning the physiologic and pharmacologic range (Figure 25.6); (iii) diabetic patients with overt fasting hyperglycemia can not elicit a normal glucose metabolic response to even maximally stimulating plasma insulin concentrations under euglycemic conditions. Virtually all investigators have demonstrated that lean type 2 diabetic subjects are resistant to the action of insulin [48,86,157–160,163,169,172–175].

The ability of glucose (hyperglycemia) to stimulate its own uptake, that is, the mass action effect of hyperglycemia, is also impaired in T2DM [176].

Site of insulin resistance in type 2 diabetes

Both the liver and muscle are severely resistant to insulin in individuals with T2DM (reviewed in [1–3]). However, when discussing insulin resistance, it is important to distinguish what is responsible for the insulin resistance in the basal or fasting state and what is responsible for the insulin resistance in the insulin-stimulated state.

Liver. The brain and all nueronal tissues have an obligate need for glucose and are responsible for ~50% of glucose utilization under basal or fasting conditions [4,5]. This glucose demand is met primarily by glucose production by the liver (80–90%) and to a smaller extent by the kidneys [4]. Following an overnight fast, the liver of nondiabetic individuals produces glucose at the rate of ~2.0 mg kg^{-1} per min [1–3,38] (Figure 25.7). In T2DM individuals, the basal rate HGP is increased, averaging ~2.5 mg kg^{-1} per min [1–3,38] (Figure 25.7). This amounts to the addition of an extra 25–30 g of glucose to the systemic circulation every night in a 80-kg person. In healthy control subjects the fasting plasma glucose concentration is ~85–90 mg dL^{-1},

and their basal rate of HGP averages ~2 mg kg^{-1} per min. In type 2 diabetic subjects, the fasting plasma glucose concentration rises in direct proportion to the increase in the basal rate of hepatic glucose production ($r = 0.847$, $p < 0.001$). This excessive production of glucose by the liver occurs despite fasting plasma insulin levels that are increased 2.5- to threefold, indicating severe resistance to the suppressive effect of insulin on HGP. Similar observations consistently have been made by others [40,177–181]. The increase in basal HGP is explained entirely by an increase in hepatic gluconeogenesis [182–184]. In addition to hepatic insulin resistance, multiple other factors contribute to the accelerated rate of basal HGP including: (i) increased circulating glucagon levels and enhanced hepatic sensitivity to glucagon [185–187]; (ii) lipotoxicity leading to increased expression and activity of phosphoenolpyruvate carboxykinase and pyruvate carboxylase [188], the rate-limiting enzymes for gluconeogenesis; and (iii) increased expression and activity of glucose-6-phosphatase, the rate-limiting enzyme for glucose escape from the liver. In rodents the increase G6Pase activity has been shown to result from glucotoxcity [189].

During a mixed meal or following glucose ingestion, the liver of type 2 diabetic patients is also resistant to the suppressive effect of insulin on HGP [40,190]. Using the euglycemic insulin clamp [191] in combination with isotopic glucose, the dose-response relationship between hepatic glucose production and the plasma insulin concentration has been examined [12] (Figure 25.8). The following points deserve emphasis: (i) the dose-response curve relating to inhibition of HGP to the plasma
Figure 25.8 Dose-response curve relating the plasma insulin concentration to the suppression of HGP in control (solid circles, solid line) and type 2 diabetic (open circles, dashed line) subjects with moderately severe fasting hyperglycemia. *$p < 0.05$, **$p < 0.01$ vs. control subjects. Figure 25.9 Time course of change in leg glucose uptake in type 2 diabetic (open circles, dashed line) and control (solid circles, solid line) subjects. In the postabsorptive state, glucose uptake in the diabetic group was significantly greater than that in control subjects. However, the ability of insulin (euglycemic insulin clamp) to stimulate leg glucose uptake was reduced by 50% in the diabetic subjects. Source: DeFronzo RA, et al. *Journal of Clinical Investigation* 1985;**76**:149–155. Reproduced with permission of American Society for Clinical Investigation.

insulin level is very steep, with a half-maximal insulin concentration (ED50) of ~30–40 µU mL^{-1}; (ii) in type 2 diabetic subjects the dose-response curve is shifted rightward, indicating resistance to the inhibitory effect of insulin on hepatic glucose production. However, elevation of the plasma insulin concentration to the high physiologic range (~100 µU mL^{-1}) can overcome the hepatic insulin resistance and cause a near normal suppression of HGP; (iii) the severity of the hepatic insulin resistance is related to the level of glycemic control. In type 2 diabetic patients with mild fasting hyperglycemia, an increment in plasma insulin concentration of 100 µU mL^{-1} causes a complete suppression of HPG. However, in diabetic subjects with more severe fasting hyperglycemia, the ability of the same plasma insulin concentration to suppress HGP is impaired. These observations indicate that there is an acquired component of hepatic insulin resistance, which becomes progressively worse as the diabetic state decompensates over time.

The kidney possesses all of the gluconeogenesis enzymes required to produce glucose and estimates of the renal contribution to total endogenous glucose production have varied from 5% to 20% [192,193]. These varying estimates of the contribution of renal gluconeogenesis to total glucose production are, in large part, related to differences in the methodology employed to measure renal glucose production [194]. One study suggests that the basal rate of renal gluconeogenesis is increased in type 2 diabetics and contributes to the elevation in fasting plasma glucose concentration [195]. However, studies employing the hepatic vein catheter technique have shown that all of the increase in total body endogenous glucose production (measured with 3-^{3}H-glucose) in type 2 diabetics can be accounted for by increased hepatic glucose output (measured by the hepatic vein catheter technique) [6].

Muscle. Muscle is the major site of insulin-mediated glucose disposal in humans [1–3,6]. Using the euglycemic insulin clamp technique [191] in combination with tritiated glucose to measure total body glucose disposal

[1–3,6,19,28,32,39,41,60,61,177,181,196–199], it has been conclusively demonstrated that lean type 2 diabetic individuals are severely resistant to insulin compared with age-, weight-, and sex-matched control subjects. Employing femoral arterial and venous catheterization in combination with the insulin clamp, muscle insulin resistance has been shown to account for over 85–90% of the impairment in total body glucose disposal in type 2 diabetic subjects [6,36] (Figure 25.9). There is a significant delay (20–30 min) in the muscle's response to insulin. However, even if the insulin clamp is extended for an additional hour in diabetic subjects to account for the delay in onset of insulin action, the rate of insulin-stimulated glucose disposal remains 50% less than in control subjects. A similar defect in insulin-stimulated muscle glucose uptake in type 2 diabetic subjects has been demonstrated using the limb catheterization technique [36,200–203].

In type 2 diabetic subjects multiple intramyocellular defects in insulin action have been demonstrated (revised in [1–3,42]), including impaired glucose transport and phosphorylation [36,203–206], reduced glycogen synthesis [205–208], and decreased glucose oxidation [39,209]. However, more proximal defects in the insulin signal transduction system play a paramount role in the muscle insulin resistance [42,210,211].)

Insulin signal transduction. For insulin to work, it must first bind to and then activate the insulin receptor by phosphorylating key tyrosine residues on the β chain [42,211–214] (Figure 25.10). This results in the translocation of insulin receptor substrate (IRS)-1 to the plasma membrane, where it interacts with the insulin receptor and also undergoes tyrosine phosphorylation. This leads to the activation of PI-3 kinase and Akt, resulting in glucose transport into the cell, activation of nitric oxide synthase with arterial vasodilation [215–217], and stimulation of multiple intracellular metabolic processes.

Studies by DeFronzo and colleagues were the first to demonstrate in humans that the ability of insulin to tyrosine phosphorylate IRS-1 was severely impaired in lean type
Figure 25.10 Insulin signaling pathway in healthy subjects.
Figure 25.11 Consequences of impaired insulin signaling in individuals with type 2 diabetes mellitus. See text for more detailed description.

2 diabetic individuals [42,210,211,218], in obese normal glucose-tolerant individuals [210], and in the insulin-resistant, normal glucose-tolerant offspring of two type 2 diabetic parents [219] (Figure 25.11). Similar defects have been demonstrated by others in human muscle [37,220–223]. The defect in insulin signaling leads to decreased glucose transport, impaired release of nitric oxide with endothelial dysfunction, and multiple defects in intramyocellular glucose metabolism.

In contrast to the severe defect in IRS-1 activation, the mitogen-activated protein (MAP) kinase pathway, which can be activated by Shc, is normally responsive to insulin [210] (Figure 25.11). The MAP kinase pathway, when stimulated, leads to the activation of a number of intracellular pathways involved in inflammation, cellular proliferation, and atherosclerosis [211,224–226]. The block at the level of IRS-1 impairs glucose transport into the cell and the resultant hyperglycemia stimulates insulin secretion. Because the MAP kinase pathway retains its sensitivity to insulin [210,211,220,226], this causes excessive stimulation of this pathway and activation of multiple intracellular pathways involved in inflammation and atherogenesis. This, in part, may explain the strong association between insulin resistance and atherosclerotic cardiovascular disease in nondiabetic, as well as in type 2 diabetic, individuals [211,227–232]. The only class of oral antidiabetic

drugs—the TZDs—that simultaneously augment insulin signaling through IRS-1 and inhibit the MAP kinase pathways is the thiazolidinediones [218].

Route of glucose administration: oral versus intravenous. The euglycemic insulin clamp, by maintaining plasma glucose and insulin levels constant, has become the gold standard for quantitating insulin sensitivity. However, the normal route of glucose administration in every day life is via the gastrointestinal tract. Using a double tracer technique (1-^{14}C-glucose orally and 3-^{3}H-glucose intravenously) in combination with hepatic vein catheterization, the disposal of oral versus i.v. glucose has been examined in healthy, normal glucose-tolerant and type 2 diabetic subjects [6,40,190,196,233]. Under basal conditions, with fasting plasma glucose and insulin concentrations of $90\,mg\,dL^{-1}$ and $11\,mU\,mL^{-1}$, respectively, the splanchnic tissues, which primarily reflect the liver, take up glucose at the rate of $0.5\,mg\,kg^{-1}$ per min (Figure 25.12). When insulin is administered intravenously in subjects with NGT to raise the plasma insulin concentration to $1189\,\mu U\,mL^{-1}$ while maintaining euglycemia, no stimulation of hepatic glucose uptake is observed. When insulin is infused with glucose to elevate both glucose and insulin levels, hepatic glucose uptake is increased, but only in proportion to the increase in plasma glucose concentration, despite plasma insulin concentrations in excess of $1000\,\mu U\,mL^{-1}$. In contrast, oral glucose administration augments hepatic glucose uptake 4.5-fold, despite plasma insulin and glucose concentrations that are much lower than with i.v. glucose plus insulin administration (Figure 25.12). If the same oral glucose load is administered to type 2 diabetic individuals, despite higher plasma glucose and insulin concentrations than in nondiabetic subjects, hepatic glucose uptake is reduced by >50%. These results indicate that T2DM individuals lack the gut factor responsible for enhancing hepatic glucose uptake following glucose ingestion.

Summary: pathogenesis. In summary, impaired insulin secretion, decreased muscle glucose uptake, increased HGP, and
Figure 25.12 Hepatic glucose uptake in nondiabetic and diabetic (DIAB) subjects as a function of plasma glucose and insulin concentration and route of glucose administration. decreased hepatic glucose uptake all contribute to the glucose intolerance in type 2 diabetic individuals

Cellular mechanisms of insulin resistance

The cellular events via which insulin initiates its stimulatory effect on glucose metabolism start with binding of the hormone to specific receptors that are present on the cell surface of all insulin target tissues [1–3,211–214]. After insulin has bound to and activated its receptor, "second messengers" are generated and these second messengers activate a cascade of phosphorylation-dephosphorylation reactions that result in stimulation of intracellular glucose metabolism. The first step in glucose utilization involves activation of the glucose transport system, leading to glucose influx into insulin target tissues, primarily muscle. The free glucose, which has entered the cell, subsequently is metabolized by a series of enzymatic steps that are under the control of insulin. Of these, the most important are glucose phosphorylation (catalyzed by hexokinase), glycogen synthase (which controls glycogen synthesis), and phosphofructokinase (PFK) and PDH (which regulate glycolysis and glucose oxidation, respectively).

Insulin receptor/insulin receptor tyrosine kinase
The insulin receptor is a glycoprotein which consists of two α-subunits and two β-subunits linked by disulfide bonds [1–3, 211–214] (Figure 25.10). The two α-subunits of the insulin receptor are entirely extracellular and contain the insulin-binding domain. The β-subunits have an extracellular domain, a transmembrane domain, and an intracellular domain that expresses insulin-stimulated kinase activity directed towards its own tyrosine residues. Phosphorylation of the β-subunit, with subsequent activation of insulin receptor tyrosine kinase, represents the first step in the action of insulin on glucose metabolism. Mutagenesis of any of the three major phosphorylation sites (at residues 1158, 1163, and 1162) impairs insulin receptor kinase activity, leading a decrease in the metabolic and growth promoting effects of insulin [234].

Insulin receptor signal transduction
Following its activation, insulin receptor tyrosine kinase phosphorylates specific intracellular proteins, of which at least nine have been identified [212,213,235]. In muscle insulin-receptor substrate-1 (IRS-1) serves as the major docking protein that interacts with the insulin receptor tyrosine kinase and undergoes tyrosine phosphorylation in regions containing specific amino acid sequence motifs that, when phosphorylated, serve as recognition sites for proteins containing *src*-homology 2 (SH2) domains. Mutation of these specific tyrosines severely impairs the ability of insulin to stimulate muscle glycogen synthesis, glucose oxidation, and other acute metabolic and growth promoting effects of insulin [234]. In liver, IRS-2 serves as the primary docking protein that undergoes tyrosine phosphorylation and mediates the effect of insulin on hepatic glucose production, gluconeogenesis, and glycogen formation [236].

In muscle, the phosphorylated tyrosine residues of IRS-1 mediate an association with the 85-kDa regulatory subunit of phosphatidylinositol-3 kinase (PI-3 kinase), leading to activation of the enzyme [1–3,211–214,220,237] (Figure 25.10). PI-3 kinase is comprised of an 85-kDa regulatory subunit and a 110-kDa catalytic subunit. The latter catalyzes the 3-prime phosphorylation of phosphatidylinositol (PI), PI-4-phosphate, and PI-4,5-diphosphate, resulting in the stimulation of glucose transport. Activation of PI-3 kinase by phosphorylated IRS-1 also leads to activation of glycogen synthase, via a process that involves activation of PKB/Akt and subsequent inhibition of kinases, such as glycogen synthase kinase (GSK)-3, and activation of protein phosphatase 1 (PP1). Inhibitors of PI-3 kinase impair glucose transport and block the activation of glycogen synthase and hexokinase (HK)-II expression [211–214,220,237–239]. The action of insulin to increase protein synthesis and inhibit protein degradation also is mediated by PI-3 kinase.

Other proteins with SH2 domains, including the adapter protein Grb2 and *Shc*, also interact with IRS-1 and become phosphorylated following exposure to insulin [211–214,220]. Grb2 and *Shc* link IRS-1/IRS-2 to the mitogen-activated protein (MAP) signaling pathway (Figure 25.11), which plays an important role in the generation of transcription factors and promotes cell growth, proliferation, and differentiation [212,220]. Inhibition of the MAP kinase pathway prevents the stimulation of cell growth by insulin but has no effect on the metabolic actions of the hormone [240].

Under anabolic conditions insulin augments glycogen synthesis by simultaneously activating glycogen synthase and inhibiting glycogen phosphorylase [241,242]. The effect of insulin is mediated via the PI-3 kinase pathway which inactivates kinases, such as glycogen synthase kinase-3, and activates phosphatases, particularly protein phosphatase 1 (PP1). PP1 is believed to be the primary regulator of glycogen metabolism. In skeletal muscle, PP1 associates with a specific glycogen-binding regulatory subunit, causing dephosphorylation (activation) of glycogen synthase. PP1 also phosphorylates (inactivates) glycogen phosphorylase. Multiple studies have demonstrated convincingly that inhibitors of PI-3 kinase inhibit glycogen synthase activity and abolish glycogen synthesis [213,243].

Insulin receptor signal transduction defects in type 2 diabetes
Insulin receptor number and affinity
Both receptor and postreceptor defects contribute to insulin resistance in individuals with T2DM. Some studies have demonstrated a modest 20–30% reduction in insulin binding to monocytes and adipocytes from T2DM patients, but this has not been a consistent finding [1–3,244–247]. The decrease in insulin binding is due to a reduction in the number of

insulin receptors without change in insulin receptor affinity. However, caution should be employed in interpreting these studies, since muscle and liver, not adipocytes, are the major tissues responsible for the regulation of glucose homeostasis *in vivo* and insulin binding to solubilized receptors obtained from skeletal muscle and liver has been shown to be normal in obese and lean diabetic individuals [245,246,248]. Moreover, a decrease in insulin receptor number cannot be demonstrated in over half of type 2 diabetic subjects, and it has been difficult to demonstrate a correlation between reduced insulin binding and the severity of insulin resistance [249–251]. A variety of defects in insulin receptor internalization and processing have been described in syndromes of severe insulin resistance and diabetes. However, the insulin receptor gene has been sequenced in T2DM patients from diverse ethnic populations and, with very rare exceptions, physiologically significant mutations in the insulin receptor gene have not been observed [252,253]. This excludes a structural gene abnormality in the insulin receptor as a cause of common T2DM.

Insulin receptor tyrosine kinase activity

Insulin receptor tyrosine kinase activity has been examined in skeletal muscle, adipocytes, and hepatocytes from normal-weight and obese diabetic subjects. Most [1–3,210, 246,249,254], but not all [248], investigators have found a reduction in tyrosine kinase activity (Figure 25.11) that cannot be explained by alterations in insulin receptor number or insulin receptor binding affinity. However, restoration of normoglycemia by weight loss has been shown to correct the defect in insulin receptor tyrosine kinase activity [255], suggesting that the defect in tyrosine kinase is acquired secondary to some combination of hyperglycemia, distributed intracellular glucose metabolism, hyperinsulinemia, and insulin resistance—all of which improved after weight loss. Exposure of cultured fibroblasts to high glucose concentration also inhibits insulin receptor tyrosine kinase activity [256]. Since insulin receptor tyrosine kinase activity assays are performed *in vitro*, the results of these assays could provide misleading information with regard to insulin receptor function *in vivo*. To circumvent this problem, investigators have employed the euglycemic hyperinsulinemic clamp with muscle biopsies and antiphosphotyrosine immunoblot analysis to provide a "snapshot" of the insulin-stimulated tyrosine phosphorylation state of the receptor *in vivo* [210]. In insulin-resistant obese nondiabetic and type 2 diabetic subjects a substantial decrease in insulin receptor tyrosine phosphorylation has been demonstrated. However, when insulin-stimulated insulin receptor tyrosine phosphorylation was examined in normal glucose-tolerant, insulin-resistant individuals (offspring of two diabetic parents) at high risk of developing T2DM, a normal increase in tyrosine phosphorylation of the insulin receptor was observed [219]. These findings are consistent with the concept that impaired insulin receptor tyrosine kinase activity in type 2 diabetic

patients is acquired secondary to hyperglycemia or some other metabolic disturbance.

Insulin signaling (IRS-1 and PI-3 kinase) defects

In insulin-resistant obese nondiabetic subjects, the ability of insulin to activate insulin receptor and IRS-1 tyrosine phosphorylation in muscle is modestly reduced, while in T2DM individuals insulin-stimulated insulin receptor and IRS-1 tyrosine phosphorylation are severely impaired [210] (Figure 25.11). Association of the p85 subunit of PI-3 kinase with IRS-1 and activation of PI-3 kinase also are greatly attenuated in obese nondiabetic and type 2 diabetic subjects compared to lean healthy controls [210,220,221] (Figure 25.11). The decrease in insulin-stimulated association of the p85 regulatory subunit of PI-3 kinase with IRS-1 is closely correlated with the reduction in insulin-stimulated muscle glycogen synthase activity and *in vivo* insulin-stimulated glucose disposal [210]. Impaired regulation of PI-3 kinase gene expression by insulin also has been demonstrated in skeletal muscle and adipose tissue of type 2 diabetic subjects [257]. In animal models of diabetes, an 80–90% decrease in insulin-stimulated IRS-1 phosphorylation and PI-3 kinase activity has been reported [258].

In the insulin-resistant, normal glucose-tolerant offspring of two type 2 diabetic parents, IRS-1 tyrosine phosphorylation and the association of p85 protein/PI-3 kinase activity with IRS-1 are markedly decreased despite normal tyrosine phosphorylation of the insulin receptor; these insulin signaling defects are correlated closely with the severity of insulin resistance, measured with the euglycemic insulin clamp technique [219]. In summary, impaired association of PI-3 kinase with IRS-1 and its subsequent activation are characteristic abnormalities in type 2 diabetics, and these defects are correlated closely with *in vivo* muscle insulin resistance. A common mutation in the IRS-1 gene (Gly 972 Arg) has been associated with T2DM, insulin resistance, and obesity, but the physiologic significance of this mutation remains to be established [259].

Insulin resistance of the PI-3 kinase signaling pathway contrasts with an intact stimulation of the MAP kinase pathway by insulin in insulin-resistant type 2 diabetic and obese nondiabetic individuals [1–3,209–211,220]. Physiologic hyperinsulinemia increases MEK1 activity and ERK1/2 phosphorylation and activity similarly in lean healthy subjects and in insulin-resistant obese nondiabetic and type 2 diabetic patients. Intact stimulation of the MAP kinase pathway by insulin in the presence of insulin resistance in the PI-3 kinase pathway may play an important role in the development of atherosclerosis [210]. If the metabolic (PI-3 kinase) pathway is impaired, plasma glucose levels rise, resulting in increased insulin secretion and hyperinsulinemia. Because insulin receptor function is normal or only modestly impaired, especially early in the natural history of T2DM, this leads to excessive stimulation of the MAP kinase (mitogenic) pathway in vascular tissues, with resultant proliferation of vascular smooth muscle

cells, increased collagen formation, and increased production of growth factors and inflammatory cytokines [211,226,260].

Glucose transport

Activation of the insulin signal transduction system in insulin target tissues stimulates glucose transport via a mechanism that involves translocation of a large intracellular pool of glucose transporters (associated with low-density microsomes) to the plasma membrane and their subsequent activation after insertion into the cell membrane [261,262]. There are five major facilitative glucose transporters with distinctive tissue distributions [263,264] (Table 25.2). GLUT4, the insulin regulatable transporter, is found in insulin-sensitive tissues (muscle and adipocytes), has a K_m of $\sim 5\,mmol\,L^{-1}$ which is close to that of the plasma glucose concentration, and is associated with hexokinase (HK)-II [263,264]. In adipocytes and muscle, GLUT4 concentration in the plasma membrane increases markedly after exposure to insulin, and this increase is associated with a reciprocal decline in the intracellular GLUT4 pool. GLUT1 is the predominant glucose transporter in the insulin-independent tissues (brain and erythrocytes), but is also found in muscle and adipocytes. GLUT1 is located primarily in the plasma membrane, where its concentration is unchanged following exposure to insulin. It has a low K_m ($\sim 1\,mmol\,L^{-1}$) and is well suited for its function, which is to mediate basal glucose uptake. It is found in association with HKI [265]. GLUT2 is the predominant transporter in liver and pancreatic β cells, where it is found in association with a specific hexokinase, HKIV or glucokinase [266]. GLUT2 has a very high K_m (~ 15–$20\,mmol\,L^{-1}$), which allows the glucose concentration in cells expressing this transporter to rise in direct proportion to the increase in plasma glucose concentration. This unique characteristic allows these cells to function as glucose sensors.

In adipocytes and muscle of type 2 diabetic patients glucose transport activity is severely impaired [220,249,261,262,267,268]. In adipocytes from human and rodent models of T2DM, GLUT4 mRNA and protein content are markedly reduced, and the

Table 25.2 Classification of glucose transport and HK activity according to their tissue distribution and functional regulation

Organ	Glucose transporter	HK	Classification
Brain	GLUT1	HK-I	Glucose dependent
Erythrocyte	GLUT1	HK-I	Glucose dependent
Adipocyte	GLUT4	HK-II	Insulin dependent
Muscle	GLUT4	HK-II	Insulin dependent
Liver	GLUT2	HK-IVL	Glucose sensor
GK β cell	GLUT2 HK-IVB (glucokinase)		Glucose sensor
Gut	GLUT3-symporter	—	Sodium dependent
Kidney	GLUT3-symporter	—	Sodium dependent

Source: DeFronzo RA. Pathogenesis of type 2 diabetes: metabolic and molecular implications for identifying genes. *Diabetes Reviews* 1997;**5**:177–269.

ability of insulin to elicit a normal translocation response and to activate the GLUT4 transporter after insertion into the cell membrane is decreased. In contrast to adipocytes, muscle tissue from lean and obese type 2 diabetic subjects exhibits normal levels of GLUT4 mRNA expression and normal levels of GLUT4 protein, thus demonstrating that transcriptional and translational regulation of GLUT4 is not impaired [269,270]. In contrast to the normal expression of GLUT4 protein and mRNA in muscle of type 2 diabetic subjects, every study that has examined adipose tissue has reported reduced basal and insulin-stimulated GLUT4 mRNA levels and decreased GLUT4 transporter number in all subcellular fractions. These observations demonstrate that GLUT4 expression in humans is subject to tissue-specific regulation. Using a novel triple-tracer technique, the *in vivo* dose-response curve for the action of insulin on glucose transport in forearm skeletal muscle has been examined in type 2 diabetic subjects and insulin-stimulated inward muscle glucose transport has been shown to be severely impaired [36,203,271]. Impaired *in vivo* muscle glucose transport in type 2 diabetics has also been demonstrated using MRI [200] and PET [272]. Since the number of GLUT4 transporters in the muscle of diabetic subjects is normal, impaired GLUT4 translocation and decreased intrinsic activity of the glucose transporter are responsible for the defect in muscle glucose transport. Large populations of type 2 diabetics have been screened for mutations in the GLUT4 gene [273]. Such mutations are very uncommon and, when detected, have been of questionable physiologic significance.

Glucose phosphorylation

Glucose phosphorylation and glucose transport are tightly coupled phenomena [274]. Hexokinase isoenzymes (HK-I–HK-IV) catalyze the first committed step of glucose metabolism, the intracellular conversion of free glucose to glucose-6-phosphate [263–265,275] (G-6-P) (Table 25.2). HK-I, HK-II, and HK-III are single-chain peptides that have a very high affinity for glucose and demonstrate product inhibition by (G-6-P). HK-IV, also called glucokinase, has a lower affinity for glucose and is not inhibited by G-6-P. Glucokinase (HK-IVB) represents the glucose sensor in the β cell, while HK-IVL in the liver plays a central role in the regulation of hepatic glucose metabolism.

In human skeletal muscle, HK-II transcription is regulated by insulin, whereas HK-I mRNA and protein levels are not affected by insulin [276–278]. In response to physiologic euglycemic hyperinsulinemia of 2–4 h duration, HK-II cytosolic activity, protein content, and mRNA levels increase by 50–200% in healthy nondiabetic subjects and this is associated with the translocation of HK-II from the cytosol to the mitochondria. In forearm muscle, insulin-stimulated glucose transport (measured with the triple tracer technique) is markedly impaired in lean type 2 diabetics [36,203,271]. However, the rate of intracellular glucose phosphorylation is impaired to an even greater extent, resulting in an increase in the free glucose concentration within the intracellular space that is accessible

to glucose. These observations indicate that in type 2 diabetic individuals, while both glucose transport and glucose phosphorylation are severely resistant to the action of insulin, impaired glucose phosphorylation (HK-II) appears to be the rate-limiting step for insulin action. Studies using ^{31}P-NMR in combination with 1-^{14}C-glucose have also demonstrated that both insulin-stimulated muscle glucose transport and glucose phosphorylation are impaired in type 2 diabetic subjects, but results from this study suggest that the defect in transport exceeds the defect in phosphorylation [205]. Because of methodologic differences, the results of the triple tracer [36,203,271] and MRI [205] studies cannot be reconciled at present. Nonetheless, these studies are consistent in demonstrating that abnormalities in both muscle glucose phosphorylation and glucose transport are well established early in the natural history of T2DM and cannot be explained by glucose toxicity.

In healthy nondiabetic subjects, a physiologic increase in the plasma insulin concentration for as little as 2–4 hours increases muscle HK-II activity, gene transcription, and translation [276]. In lean type 2 diabetics the ability of insulin to augment HK-II activity and mRNA levels is markedly reduced compared to controls [277]. Decreased basal muscle HK-II activity and mRNA levels and impaired insulin-stimulated HK-II activity in type 2 diabetic subjects have been reported by other investigators [278,279]. A decrease in insulin-stimulated muscle HK-II activity has also been described in subjects with IGT [280]. Several groups have looked for point mutations in the *HKII* gene in individuals with T2DM and, although several nucleotide substitutions have been found, none are close to the glucose and ATP binding sites and none have been associated with insulin resistance [280–282]. Thus, an abnormality in the *HKII* gene is unlikely to explain the inherited insulin resistance in common variety T2DM mellitus.

Glycogen synthesis

Following phosphorylation by HK-II, glucose either can be converted to glycogen or enter the glycolytic pathway. Of the glucose that enters the glycolytic pathway, ~90% is oxidized and the remaining 10% is released as lactate. At low physiologic plasma insulin concentrations, glycogen synthesis and glucose oxidation contribute approximately equally to glucose disposal. However, with increasing plasma insulin concentrations, glycogen synthesis predominates [1–3,283]. Impaired insulin-stimulated glycogen synthesis is a characteristic finding in all insulin-resistant states including obesity, IGT, diabetes, and diabesity in all ethnic groups and accounts for the majority of the defect in insulin-mediated whole body glucose disposal [1–3,12,162,284–287]. Impaired glycogen synthesis also has been documented in the normal glucose-tolerant offspring of two diabetic parents, in the first-degree relatives of type 2 diabetic individuals, and in the normoglycemic twin of a monozygotic twin pair in which the other twin has T2DM [162,288,289].

Glycogen synthase is the key insulin-regulated enzyme which controls the rate of muscle glycogen synthesis [241, 243,278,289–291]. Insulin actives glycogen synthase by stimulating a cascade of phosphorylation-dephosphorylation reactions, which ultimately lead to the activation of PP1 (also called glycogen synthase phosphatase). The regulatory subunit of PP1 has two serine phosphorylation sites. Phosphorylation of site 2 by cAMP-dependent kinase (PKA) inactivates PP1, while phosphorylation of site 1 by insulin activates PP1, leading to the stimulation of glycogen synthase. Phosphorylation of site 1 of PP1 by insulin in muscle is catalyzed by insulin-stimulated protein kinase 1 (ISPK-1). Because of their central role in muscle glycogen formation, the three enzymes—glycogen synthase, PP1, ISPK-1—have been extensively studied in the individuals with T2DM.

Glycogen synthase exists in an active (dephosphorylated) and an inactive (phosphorylated) form [241–243]. Under basal conditions, total glycogen synthase activity in type 2 diabetic subjects is reduced and the ability of insulin to activate glycogen synthase is severely impaired [210,292–294]. The ability of insulin to stimulate glycogen synthase is also diminished in the normal glucose-tolerant, insulin-resistant relatives of type 2 diabetic individuals [295]. In insulin-resistant nondiabetic and diabetic Pima Indians activation of muscle PP1 (glycogen synthase phosphatase) by insulin is severely reduced [296]. Since PP1 dephosphorylates glycogen synthase, leading to its activation, the defect in PP1 plays an important role in the muscle insulin resistance of T2DM.

The effect of insulin on glycogen synthase gene transcription and translation *in vivo* has been studied extensively. Most studies have demonstrated that insulin does not increase glycogen synthase mRNA or protein expression in human muscle [276,297,298]. However, glycogen synthase mRNA and protein levels are decreased in muscle of type 2 diabetic patients, explaining in part the decreased glycogen synthase activity [298,299]. The major abnormality in glycogen synthase regulation in T2DM is its lack of dephosphorylation and activation by insulin, as a result of insulin receptor signaling abnormalities (see previous discussion).

The glycogen synthase gene has been the subject of intensive investigation, and DNA sequencing has revealed either no mutations or rare nucleotide substitutions that cannot explain the defect in insulin-stimulated glycogen synthase activity [300–302]. The genes encoding the catalytic subunits of PP1 and ISPK-1 have been examined in Pima Indians and Danes with T2DM [303,304]. Several silent nucleotide substitutions were found in the PP1 and ISPK-1 genes in the Danish population, but the mRNA levels of both genes were normal in skeletal muscle. No structural gene abnormalities in the catalytic subunit of PP1 were detected in Pima Indians. Thus, neither mutations in the PP1 and ISPK-1 genes nor abnormalities in their translation can explain the impaired enzymatic activities of glycogen synthase and PP1 that have been observed *in vivo*. Similarly, there is no evidence that an alteration in glycogen

phosphorylase plays any role in the abnormality in glycogen formation in T2DM [305].

In summary, glycogen synthase activity is severely impaired in type 2 diabetic individuals, but the molecular etiology of the defect remains to be determined.

Glycolysis/glucose oxidation

Glucose oxidation accounts for ~90% of total glycolytic flux, while anaerobic glycolysis accounts for the other 10%. Two enzymes, phosphofructokinase (PFK) and pyruvate dehydrogenase (PDH), play pivotal roles in the regulation of glycolysis and glucose oxidation, respectively. In type 2 diabetic individuals the glycolytic/glucose oxidative pathway has been show to be impaired [286]. Although one study has suggested that PFK activity is modestly reduced in muscle biopsies from type 2 diabetic subjects [306], most evidence indicates that the activity of PFK is normal [293,298]. Insulin has no effect on muscle PFK activity, mRNA levels, or protein content in either nondiabetic or diabetic individuals [298]. PDH is a key insulin-regulated enzyme whose activity in muscle is acutely stimulated by insulin [307]. In type 2 diabetic patients, insulin-stimulated PDH activity is decreased in human adipocytes and in skeletal muscle [307,308].

Obesity and T2DM are associated with accelerated FFA turnover and oxidation [1–3,12,309], which would be expected, according to the Randle cycle [310], to inhibit PDH activity and consequently glucose oxidation. Therefore, it is likely that the observed defects in glucose oxidation and PDH activity are acquired secondary to increased FFA oxidation and feedback inhibition of PDH by elevated intracellular levels of acetyl-CoA and reduced availability of NAD. Consistent with this scenario, the rates of basal and insulin-stimulated glucose oxidation are not reduced in the normal glucose-tolerant offspring of two diabetic parents and in the first-degree relatives of type 2 diabetic subjects, while it is decreased in overtly diabetic subjects.

Summary

In summary, postbinding defects in insulin action primarily are responsible for the insulin resistance in T2DM. Diminished insulin binding, when present, is modest and secondary to downregulation of the insulin receptor by chronic hyperinsulinemia. In type 2 diabetic patients with overt fasting hyperglycemia, a number of postbinding defects have been demonstrated, including reduced insulin receptor tyrosine kinase activity, insulin signal transduction abnormalities, decreased glucose transport, diminished glucose phosphorylation, and impaired glycogen synthase activity. The glycolytic/glucose oxidative pathway is largely intact and, when defects are observed, they appear to be acquired secondary to enhanced FFA/lipid oxidation. From the quantitative standpoint, impaired glycogen synthesis represents the major pathway responsible for the insulin resistance in T2DM, and is present long before the onset of overt diabetes, that is, in normal glucose-tolerant,

insulin-resistant prediabetic subjects and in individuals with IGT. The impairment in glycogen synthase activation appears to result from a defect in the ability of insulin to phosphorylate IRS-1, causing a reduced association of the p85 subunit of PI-3 kinase with IRS-1 and decreased activation of the enzyme PI-3 kinase.

The adipocyte, FFA metabolism, and lipotoxicity

Considerable evidence implicates deranged adipocyte metabolism and altered fat topography in the pathogenesis of glucose intolerance in T2DM [1–3,39,110,197,311–314]: (i) fat cells are resistant to insulin's antilipolytic effect, leading to day-long elevation in the plasma FFA concentration [1–3,39,110,208,311–315]; (ii) chronically increased plasma FFA levels stimulate gluconeogenesis [316–318], induce hepatic/muscle insulin resistance [319–321], and impair insulin secretion [110,322]. These FFA-induced disturbances are referred to as lipotoxicity; (iii) dysfunctional fat cells produce excessive amounts of insulin resistance–inducing, inflammatory, and atherosclerotic-provoking adipocytokines and fail to secrete normal amounts of insulin-sensitizing adipocytokines such as adiponectin [311,312]; (iv) enlarged fat cells are insulin resistant and have diminished capacity to store fat [323,324]. When adipocyte storage capacity is exceeded, lipid "overflows" into muscle, liver, and β cells, causing muscle/hepatic insulin resistance and impaired insulin secretion (reviewed in [311] and [312]). This represents another form of lipotoxicity. Lipid can also overflow into arterial vascular smooth cells, leading to the acceleration of atherosclerosis.

Using ^{14}C-palmitate in combination with the insulin clamp technique [39], the antilipolytic effect of insulin has been shown to be markedly impaired in lean type 2 diabetic subjects, as well as in obese nondiabetic subjects [208]. In both type 2 diabetic (Figure 25.13) and obese nondiabetic subjects, the ability of insulin to suppress the plasma FFA concentration and inhibit FFA turnover is impaired compared with lean normal glucose-tolerant subjects at all plasma insulin-concentrations spanning the physiologic and pharmacologic range.

Many investigators [317,318,321,325] have demonstrated that a physiologic elevation in the plasma FFA concentration stimulates HGP and impairs insulin-stimulated glucose uptake in liver [326] and muscle [318–321,325–330]. Chronically elevated plasma FFA levels also inhibit insulin secretion [110,322], especially in genetically prone individuals.

According to the Randle [310,331] cycle of substrate competition, elevated FFA oxidation in muscle reciprocally impairs glucose oxidation. Although clearly there is substrate competition between FFA and glucose with respect to oxidative metabolism [323,333], FFAs have been shown to have independent effects to inhibit glycogen synthase [334,335] and both glucose transport and glucose phosphorylation [328,336].

Further, physiologic elevation in the plasma FFA concentration for as little as 4 hours markedly impairs insulin signal transduction and inhibits insulin-mediated glucose disposal by 30–35% in healthy lean normal glucose-tolerant subjects [337]. The elevation in plasma FFA concentration caused a dose-response inhibition of muscle insulin receptor tyrosine phosphorylation, IRS-1 tyrosine phosphorylation, PI-3 kinase activity, and Akt serine phosphorylation (Figure 25.14). Conversely, reduction in the plasma FFA concentration with acipimox in T2DM individuals enhances insulin sensitivity by ∼30% in association with an increase in insulin signaling, glycogen synthesis, and glucose oxidation [338,339].

After fatty acids enter the cell, they can be converted to triglycerides, which are inert, or to toxic lipid metabolites such as fatty acyl CoAs, diacylglycerol, and ceramide [4]. Using magnetic resonance spectroscopy, the intramyocellular triglyceride content has been shown to be increased in type 2 diabetic subjects [338,340]. Fatty acyl CoAs, which are known to inhibit insulin signaling [341,342], are also significantly increased in muscle in diabetic subjects [338,343].

Peroxisome proliferator-activated γ coactivator-1 (PGC-1) is the master regulator of mitochondrial biogenesis [344] and augments the expression of multiple genes involved in mitochondrial oxidative phosphorylation [345–347]. In individuals with T2DM and in the normal glucose-tolerant, insulin-resistant offspring of two diabetic parents the expression of PGC-1, nuclear receptor factor-1, and multiple other genes involved in oxidative phosphorylation are markedly reduced in muscle and are strongly correlated with the defect in glucose oxidation and whole body (muscle) insulin resistance [211,343,348]. The reduced expression and activity of these key mitochondrial genes in the NGT offspring strongly suggests a genetic etiology for the mitochondrial dysfunction. However, there also is evidence that the mitochondrial defect is acquired, at least in part [349–351]. Treatment of diabetic patients with pioglitazone markedly improves insulin sensitivity in association with a reduction in intramyocellular lipid and fatty acyl CoA concentrations. The decrement in muscle fatty acyl CoA content is closely related to the improvement in insulin-stimulated muscle glucose disposal [340,343]. Reduced intramyocellular fatty acyl CoA content with acipimox, a potent inhibitor of lipolysis, caused a similar improvement in insulin-mediated glucose disposal [338,339]. Increased intramyocellular levels of diacylglycerol [330,352] and ceramides [353,354] have been demonstrated in type 2 diabetic and obese nondiabetic subjects and shown to be related to the insulin resistance and impaired insulin signaling in muscle. A 48-h lipid infusion, designed to increase the plasma FFA concentration ∼1.5- to twofold, inhibits the expression of PGC1α, PGC1β, PDHA1, and multiple mitochondrial genes involved in oxidative phosphorylation in muscle [349], thus mimicking the pattern of gene expression observed in type 2 diabetic subjects and in the normal glucose-tolerant, insulin-resistant offspring of two type 2 diabetic parents [355,356]. Further, in mitochondria isolated from muscle of normal glucose-tolerant subjects [350] physiologic palmitoyl carnitine concentrations ($>4\,\mu mol\,L^{-1}$) caused a marked inhibition of ATP synthesis and a decrease in the inner mitochondrial membrane potential, which provides the electromotive driving force for electron transport. Collectively,

these findings provide strong support for lipotoxicity and adipocyte insulin resistance in the pathogenesis of T2DM.

Alpha cell and glucagon

It long has been known that the basal plasma glucagon concentration is elevated in type 2 diabetic individuals [184–186, 357,358]. The important contribution of elevated fasting plasma glucagon levels to the increased basal rate of HGP in type 2 diabetic individuals was provided by Baron et al. [187]. Compared with control subjects, diabetic individuals had a markedly elevated rate of basal HGP, which correlated closely with the increase in fasting plasma glucagon concentration. Somatostatin infusion reduced the plasma glucagon concentration by 44% in association with a 58% decrease in basal HGP (Figure 25.15). These results conclusively demonstrate the pivotal role of hyperglucagonemia in the pathogenesis of fasting hyperglycemia in T2DM. There also is evidence that the liver is hypersensitive to the stimulatory effect of glucagon in hepatic gluconeogenesis [185].

In normal glucose-tolerant subjects, plasma glucagon levels decline following a meal and the decrease in portal vein glucagon concentration contributes to the suppression of HGP [359]. In contrast, following ingestion of a mixed meal in T2DM patients there is a paradoxical rise in plasma glucagon concentration which antagonizes the decline in HGP, resulting in postprandial hyperglycemia [360,361]. Thus, deranged glucagon secretion by the pancreatic α cell contributes to both fasting and postprandial hyperglycemia in T2DM patients.

The kidney: increased glucose reabsorption

The kidney filters $\sim$162 g ([glomerular filtration rate $= 180$ L day^{-1}] $\times$ [fasting plasma glucose $= 900$ mg L^{-1}]) of glucose every day. Ninety percent of the filtered glucose is reabsorbed by the high capacity SGLT2 transporter in the convoluted segment of the proximal tubule, and the remaining 10% of the filtered glucose is reabsorbed by the SGLT1 transporter in the straight segment of the descending proximal tubule [362]. The result is that no glucose appears in the urine.

In T1DM and T2DM animal models, the maximal renal tubular reabsorptive capacity (Tm) for glucose is increased [363–365]. In humans with T1DM [366] and T2DM [367] the Tm for glucose is increased, and cultured human proximal renal tubular cells from T2DM patients demonstrate markedly increased levels of SGLT2 mRNA and protein and a fourfold increase in the uptake of α-methyl-d-glucopyranoside (AMG), a nonmetabolizeable glucose analogue [368] (Figure 25.16). Thus, an adaptive response by the kidney to conserve glucose, which is essential to meet the energy demands of the body, especially the brain and other neural tissues which have an obligate need for glucose, becomes maladaptive in the diabetic patient. Instead of dumping glucose in the urine to correct the hyperglycemia, the kidney chooses to hold on to the glucose. Even worse, the ability of the diabetic kidney to reabsorb glucose is augmented by an absolute increase in the renal reabsorptive capacity for glucose.

Figure 25.17 The Ominous Octet. See text for a more detailed explanation. Source: DeFronzo RA. *Diabetes* 2009;**58**:773–795.

The brain

The brain, along with its seven companions, forms the eighth component of the Ominous Octet (Figure 25.17). The current epidemic of diabetes is being driven by the epidemic of obesity [369]. Porte and colleagues [370–373] were amongst the first to demonstrate that, in rodents, insulin was a powerful appetite suppressant. Obese individuals, both diabetic and nondiabetic, have moderate-to-severe insulin resistance with compensatory hyperinsulinemia. Nonetheless, food intake is increased in obese subjects despite the presence of hyperinsulinemia which should suppress the appetite. Therefore, one could postulate that the insulin resistance in peripheral tissues also extends to the brain.

Using functional magnetic resonance imaging (MRI), the cerebral response to an ingested glucose load has been studied [374]. After glucose ingestion, two hypothalamic areas with consistent inhibition have been noted: the lower posterior hypothalamus, which contains the ventromedial nuclei, and the upper posterior hypothalamus, which contains the paraventricular nuclei. In both of these hypothalamic areas, which are key centers for appetite regulation, the magnitude of the inhibitory response following glucose ingestion was reduced in obese, insulin-resistant, normal glucose-tolerant subjects, and there was a delay in the time taken to reach the maximum inhibitory response, even though the plasma insulin response was markedly increased in the obese group. Whether the impaired functional MRI response in obese subjects contributes to or is a consequence of the insulin resistance and weight gain remains to be determined. Nonetheless, these results suggest that the brain, like other organs (liver, muscle, and fat) in the body, are resistant to insulin. Studies by Obici et al. [375,376] and others [377] in rodents have also provided evidence for cerebral insulin resistance leading to increased HGP and reduced muscle glucose uptake.

Implications for therapy

The preceding review of the pathophysiology of T2DM has important therapeutic implications (Table 25.1). First, effective treatment of T2DM will require multiple drugs used in combination to correct the multiple pathophysiologic defects. Second, the treatment should be based upon reversal of known pathogenic abnormalities and NOT simply on the reduction in HbA1c. Third, therapy must be started early in the natural history of T2DM, if progressive β-cell failure is to be prevented. The treatment of T2DM is discussed in detail in Chapters 42–46 and 48.
